Enzymes are the core for biological transformations in nature. Their structures and functions have drawn enormous attention from biologists as well as chemists since last century. The large demand of bioactive molecules and the pursuit of efficiency and greenness of synthesis have spurred the rapid development of biomimetic chemistry in the past several decades. Biomimetic asymmetric catalysis, mimicking the structures and functions of enzymes, has been recognized as one of the most promising synthetic strategies for the synthesis of valuable chiral compounds. This review summarizes the evolution of asymmetric catalysis inspired by aldolases, vitamin B_1/B_6 -dependent enzymes, NAD(P)H, flavin, hydrogenases, heme oxygenases, non-heme oxygenases, and dinuclear/multinuclear metalloenzymes in aspects of biomimetic design, catalyst development and related catalytic transformations. Those well-established synthetic approaches originating from biological reactions have demonstrated the unique prowess of biomimetic asymmetric catalysis in bridging the gap between bio-catalysis and chemical synthesis.

Asymmetric catalysis, maintaining an irreplaceable role in construction of enantioenriched compounds for chemistry, pharmaceuticals, biology, and material science over the past half-century, has become one of the most widely utilized synthetic protocols in academia [1] as well as in industry [2]. The catalysts principally cover enzymes [3] and chemical catalysts [4-6]. In recent times, global concerns on sustainable development and environmental issues require modern asymmetric catalysis to address more challenges facing cost, pollution, renewability, etc. Indeed, enzymatic asymmetric synthesis, featured with high efficiency and mild conditions, represents an intriguing approach to single-enantiomers and it has been frequently employed in medicinal chemistry, food science, and fine chemical industry [7]. However, fragile stability, substrate specificity together with the complicatedness of protein modification makes enzymatic catalysis still problematic in the synthsis of unnatural or customized chiral compounds. Conversely, despite generally being less efficient, conventional chemical catalysts also possess notable advantages such as small molecular weight, well-designed structure, high stability, and wide substrate scope [8]. And up to now chemical catalysis still dominates the synthesis of various optically active compounds. Biomimetic asymmetric catalysis aims to develop more efficient and more powerful chemical catalysis based on the concept of the imitation of the structures and functions of enzymes [9]. It may merge the advantages of biological catalysis and chemical catalysis, to achieve asymmetric transformations with high efficiency and precise control under environmentally benign conditions [10], which meets the requirements of sustainable chemistry [11] and has become an increasingly significant area of catalysis science.

Enzymes perform functions at catalytic centers (i.e., coenzymes for most of the cases) with the assistance and cooperation of the surrounding proteins. The catalytic centers usually carry out the basic catalytic function of the enzymes, which are directly relevant to the structure of biomimetic catalysts as well as the reactions promoted. The surrounding proteins build a chiral cavity for the enzymatic catalysis. An ideal biomimetic catalyst should incorporate the two aspects, however, currently biomimetic catalysis still mainly focused on the imitation of the catalytic centers. It is much more challenging to chemically construct an analog to mimick the three-dimensional catalytic cavity of enzymes. Molecular imprinting technique represents a relatively effective method for this imitation [12a]. But only inspiring performances were observed for most of the cases. Additionly, although the peptide catalysts which mimick the amino acid residues of enzymes have been well-developed recently [12b], it is out of the scope of this review. The above two aspects will not be discussed herein.

Biomimetic catalysis has attracted considerable endeavors of chemists. As early as 1930s, chemists started to simulate aldolases for organic synthesis [13]. Breslow, the pioneer of biomimetic catalysis, firstly proposed the concept of "biomimetic chemistry" in 1958 [14]. He has made many significant contributions to this field, such as demonstrating the active carbene species for vitamin B_1 catalysis for the first time [15] and the development of vitamin B_1/B_6 -based artificial enzymes for the imitation of biological transformations [16]. Innumerous other research groups from around the world have also dedicated substantial efforts to the development of biomimetic asymmetric catalysis. Many areas have already been developed into powerful synthetic tools for construction of bioactive chiral molecules.

Chiral biomimetic catalysts can be divided into organo and metallic categories [17,18], respectively mimicking nonmetalloenzymes and metalloenzymes. Representative biomimetic organocatalysts developed include aldolase-inspired chiral amines [19], vitamin B₁-based chiral N-heterocyclic carbenes [16,20], vitamin B₆-based chiral pyridoxals/pyridoxamines [16,21], biomimetic chiral NAD(P)H catalysts [22], flavin-based oxidation catalysts [23]. The widely-used biomimetic metallic catalysts are those developed based on hydrogenases [24], heme oxygenases [25], non-heme oxygenases [26], and dinuclear/multinuclear metalloenzymes [27]. This review attempts to give an overview on the development of biomimetic asymmetric catalysis. The structure and function of the original enzymes, the design and development of the biomimetic catalysts, as well as the corresponding catalytic transformations are all discussed herein. And the main challenges along with the future perspective of biomimetic asymmetric catalysis are also described at the end of the review.

2 Aldolase-based biomimetic asymmetric catalysis

2.1 Early days in mimicking aldolase

Aldol reaction is a fundamental C–C bond construction strategy in chemical and biological processes [28]. In nature, aldolases are ubiquitous enzymes that are responsible for metabolism and storage of carbohydrates *via* C–C bond cleavage and formation [29–31]. In eukaryotes, this type of enzymes, classified as type I aldolase, functions through lysine residue primary amine (Figure 1) [32,33]. There have been enduring efforts over last century in the pursuit of understanding and mimicking the catalysis of aldolase for synthetic purpose. In 1934, Pederson [13a] reported arguably the first example of aminocatalysis (named amine catalysis then) for enamine-based decarboxylation. Four years later, Westheimer reported an aminocatalysis for retro-aldol reaction [13b]. In 1970s, Hine [34] had extensively studied enamine formation using a variety of bifunctional primary

Figure 1 Cornerstones of bio-mimetic studies of Type I aldolase and the representative aminocatalysts developed since 2000 (inside) (color online).

amines. Besides chemists' model studies, biochemists have also gained in-depth understanding of aldolase. For example, Westheimer *et al.* [35] disclosed the prevalent electrostatic effect in aminocatalytic enzymes in 1959. The first structural evidence to covalent enamine intermediates in Type I aldolase was not achieved until 2001 by the work of Wilson and Wong *et al.* [36].

Parallel to the model studies, the synthetic applications of aminocatalysis was slowly caught up particularly in asymmetric catalysis. In 1971, two independent works [37,38], one by Hajos and Parrish and the other by Weichert, Sauer and Eder, reported L-proline catalysed intramolecular aldol reaction with remarkable stereoselectivity. This is sometime referred as Hajos-Parrish-Weichert-Sauer-Eder reaction, probably the longest-named reaction. In 1980s, aldolases were investigated in organic synthesis mostly by the work of Whitesides and Wong [39], and one landmark achievement along this line is the scalable synthesis of statins derivatives as cholesterol-lowering blockbuster drugs [40]. In 1995, Lerner and Barbas [41] developed a simplified aldolase, catalytic antibody 38C2, using transition-state-induced immunological approach, that showed significant application in asymmetric synthesis. Related studies on antibody aldolases also set basis for de novo computational design of retroaldolase [42].

In retrospect, type I aldolase provides chemists initial impetus to explore amine catalysis in a much earlier time, provided with its metal-free and pure organic working mode as well as the readily accessibility of small molecular amine compounds. However, it was not until 2000 when List, Barbas and Lerner [43] reported the first example on proline

catalysed intermolecular direct aldol reaction (Scheme 1, above), that enamine catalysis has started to receive recognition as a viable and general catalytic mode and eventually becomes a mainstay in asymmetric catalysis.

2.2 Aminocatalysis in the golden era of organocatalysis

2.2.1 Activation mode

The year of 2000 is iconic for the renaissance of organocatalysis. The work by List, Barbas and Lerner represented a general enamine-activation mode (HOMO raising), closely resembling its nature counterpart. In the same year, Mac-Millan *et al.* [44] designed a new chiral amine catalyst and successfully realized the first enantioselective organocatalytic Diels-Alder reaction. The reaction proceeds *via* an iminium ion activation (LUMO lowering) process (Scheme 1, below). These two seminal works disclosed two fundamental, yet complementary activation modes of aminocatalysis, which later on were proved to be generally applicable.

2.2.2 Developed aminocatalysts

Chiral secondary amines are most frequently explored in the early developing stage of aminocatalysis. Besides proline and MacMillan's imidazolinone catalyst, diphenylprolinol derivatives were first utilized as aminocatalysts by Hayashi *et al.* [45] and Jørgensen *et al.* [46] independently. H-bonding type pyrrolidines were first introduced by Gong *et al.* [47] and ionic-liquid type pyrrolidines [48] are some of the representative secondary amine catalysts. Chiral primary amine catalysts, the truly structural mimic to Type I aldolase, did not receive attention at the very beginning, mostly due to

Scheme 1 Seminal works in aminocatalyis and the general activation modes (color online).

the known fact that primary amine tends to form imine instead of enamine [49]. Some of the prevalent chiral primary amine catalysts include amino acid derivatives [50], primary amine-urea/thioureas [51], cinchona-derived primary amines [52], and vicinal primary-tertiary diamine catalysts [53] (Figure 1, inside).

2.2.3 Synthetic applications

Aminocatalysis provides an enabling tool in the direct functionalization of ketones and aldehydes *via* C–C [54] and C–X [55] bond formation. Over 20 years, the scopes have been significantly expanded as witnessed by the increasing complexity of substrates as well as the target products. The sites of functionalization can be extended from the typical α -or β -position of carbonyls to the remote γ -, δ -, or ε -position *via* new types of intermediates such as dienamine [56] or trienamine intermediates [57,58]. The mild conditions as well as functional group tolerability are well demonstrated in multi-component reactions and cascade processes [59]. There have been increasing numbers of successful applications of advanced aminocatalysis in the constructions of pharmaceuticals and natural products as featured in Figure 2 [60–68].

2.2.4 Current developing trends

As a mature field, there are still notable advances that significantly expand the reaction spaces of aminocatalysis. One of the major advances is external tuning of enamine that enables the incorporation of nucleophiles as coupling partners (Figure 3). In this strategy, enamine could be polarityreversed by single-electron-transfer *via* chemical [69], photochemical [70] or electrochemical processes [71] to give enamine radical cation or its associated species as electrophilic intermediates [72,73]. Enamines could also be tuned by photo-energy transfer to enable transformations through an excited species [74,75]. Another viable strategy is synergistic aminocatalysis by combining with other catalytic approaches (Figure 4). In this regard, the possible combinations are enormous including other chemical catalysis such as transition metal catalysts [76–85], organocatalysts [86– 88], photocatalytic systems [89] or electrochemical processes [90,91].

2.3 Recent advances in bio-inspired chiral primary amine catalysis

Though born with a biological origin traced to Type I aldolase, aminocatalyst has been evolved mainly with a focus on synthetic methodology. Chiral primary amines bear structural resemblance to the enzymatic lysine residue catalysis, and their catalysis has largely complemented those secondary aminocatalysis by their conformational flexibility, hence space tolerance of sterically hindered ketones and aldehydes. Luo et al. have developed primary-tertiary vicinal diamines as both structural and mechanistic mimics of its natural counterpart, not only mimicking six natural aldol processes [92], but also demonstrating broad applicability in a number of different transformations. Mechanistically, this type of bio-inspired primary aminocatalysis proceeds via anionproton shuttle for iminium-enamine tautomerization, a feature closely resembling the natural water-proton shuttle observed in DERA-type I aldolase [93] (Figure 5). The cavity

Figure 2 Representative drugs and natural products enabled by aminocatalysis.

Figure 3 External tuning of aminocatalytic intermediates (color online).

effect on primary aminocatalysis was also investigated in a supramolecular primary amine catalyst [94]. Representative advances with this type of primary aminocatalysts were illustrated herein.

2.3.1 Tuning secondary enamine intermediate

α-imino radical. Unlike its tertiary counterpart in singly occupied molecular orbital (SOMO) type catalysis, radical cation of secondary enamine has an acidic enaminyl N–H (pK_a <10) and tends to lose a proton to form *α*-imino radical intermediate (Figure 3). In 2017, Luo *et al.* [77] reported an *α*-imino radical catalysis with chiral primary aminocatalyst in a photocatalytic decarboxylative alkynylation reaction. Recently, they further advanced the *α*-imino radical catalysis to a dehydrogenative allylic alkyla tion reaction using a triple catalyst and Ir-based photosensitizer. Mechanism studies disclosed a cooperative radical addition process *via* a sandwich-type TS (Scheme 2, TS-1) involving a chiral *α*-imino radical and Co(II)-metalloradical.

E/Z isomerization of enamine. Besides photoinduced electron transfer, energy transfer was also found to modulate the reactivity of enamine intermediate. Very recently, Luo and coworkers [75] developed a photochemical E/Z isomerization of enamine intermediate *via* energy transfer strategy (EnT), enabling the deracemization of α -branched aldehydes by merging chiral primary aminocatalyst and a photosensitizer. Enantioenriched α -aryl aldehydes were obtained

with high efficiency and enantioselectivity. Enamine E/Z isomerization *via* EnT facilicates the conversion of the matched (*S*)-aldehyde into mismatched (*R*)-aldehyde (Scheme 3), leading to deracemization. The stereospecific iminium/enamine tautomerization *via* anion-proton shuttle is

Figure 4 Synergistic aminocatalysis with other catalytic system (color online).

Figure 5 Bio-inspired chiral primary amine catalyst and the underlying mechanism (color online).

Scheme 2 Activation of SOMO by photocatalysis and cobalt catalysis (color online).

also a key factor that underlines the stereocontrol in the whole process.

2.3.2 Synergistic catalysis with chiral primary amine

Amine/ketone cooperative catalysis. Amine and ketone are yin and yang in organocatalysis that are known to mutually transform each other. A cooperative activation between this pair is rare and has not been reported in asymmetric catalysis. In 2021, Luo's group [88] reported the first example of cooperative amine/ketone catalysis for asymmetric α -hydroxylation of β -ketocarbonyls with hydrogen peroxide. It was found that the addition of catalytic amount of trifluoroacetophenone (PhCOCF₃) could enhance the reaction rate by eight times. Mechanistic studies revealed that aminocatalyst and ketone work cooperatively to activate hydrogen peroxide in the form of oxaziridine. The reaction proceeds *via* an enamine-oxidaziridine coupling to afford the desired hydroxylation adducts in high enantioselectivity (Scheme 4).

Amine/Pd synergistic catalysis. Though amine/metal synergistic catalysis is quite established, to develop aminocatalyst endowed with distinctive coordinating feature remains elusive. In 2020, Luo's group [95] developed a chiral primary amine catalyst bearing arene as π -ligand. The asymmetric allyl alkylation of β -ketocarbonyl group can be successfully achieved by this catalytic system (Scheme 5). Compared with the typical sterically bulky aminocatalyst, π coordinating aminocatalyst can not only greatly enhance the reaction rate, but also guide facial selectivity of enamine attack, leading to the reversal of chiral induction.

Amine/photoredox synergetic catalysis. In 2017, Luo and Wu *et al.* [89] developed asymmetric cross-dehy-drogenative coupling (CDC) of tertiary amines with ketones using a triple catalytic system involving a photoredox catalyst, a chiral primary amine catalyst, and a cobaloxime co-catalyst. The cooperative photoredox/Co catalysis leads to the generation of an iminium cation intermediate, which is

Scheme 3 Deracemization through photochemical E/Z isomerization of enamines (color online).

Scheme 4 Asymmetric hydroxylation catalyzed by cooperative amineketone catalysis (color online).

Scheme 5 Chiral primary amine/Pd co-catalyzed allyl alkylation (color online).

intercepted by *in-situ* generated enamine intermediate to provide CDC products with high enantioselectivities. A repulsion model with mixed steric and charge effects were proposed to account for the high stereocontrol (Scheme 6).

Aminocatalysis in electrochemical cell. Primary aminocatalysis also works well in an electrochemical setting, further adding their green credentials by avoiding the use of chemical oxidants, meanwhile enabling novel reactivity. In 2017, Luo's group [90] reported an electrochemical version of the asymmetric cross dehydrogenative coupling of ketones and tertiary amines. In 2020, they developed an electrochemical protocol for *in-situ* oxidative generation of benzyne or cyclohexyne from 1-aminobenzotriazole and realized a catalytic asymmetric α -arylation of cyclic β -ketocarbonyls with benzynes by chiral primary aminocatalysis (Scheme 7) [91].

2.4 Summary and perspectives of aldolase-based biomimetic asymmetric catalysis

Over a centennial exploitation, chemists have excelled in mimicking natural aminocatalytic enzyme, *e.g.*, Type I aldolase, and developing privileged chiral aminocatalysts with strong biological features. Now, aminocatalysis, once an icon for the renaissance of organocatalysis, has become an established and enabling strategy in asymmetric catalysis. As illustrated in this short summary, the potentials of aminocatalysis, particularly those bio-inspired chiral primary amines, can be significantly expanded by judiciously combining with light, electricity or another catalytic system. We see no limits in the explorations along this line.

3 Vitamin **B**₁-related *N*-heterocyclic carbene catalysis

3.1 Vitamin B₁ and *N*-heterocyclic carbene

3.1.1 Vitamin B_1

Vitamin B_1 (thiamine, 1) is one of the 13 vitamins that are

Scheme 6 Asymmetric cross dehydrogenation coupling catalyzed by synergistic photoredox, cobalt catalysis and aminocatalysis (color online).

Scheme 7 Electrocatalytic asymmetric α -arylation of cyclic β -ketocarbonyls by chiral primary amine (color online).

essential for human beings. As determined by Williams and Waterman [96] in the middle of 1930s, the structure of thiamine contains a pyrimidine substituted thiazolium motif, bearing a free amino and hydroxy group (Figure 6, left). Thiamine pyrophosphate (TPP, 2) (Figure 6, right) is the most common active species of thiamine in promoting biochemical transformations. TPP is the cofactor of many important enzymes, such as transketolase, pyruvate decarboxylase, dihydroxyacetone synthase, and 1-deoxyxvlulose-5-phosphate synthase. Figure 7 shows the structure of two thiamine-dependent enzymes (transketolase and pyruvate decarboxylase), in which thiamine is embedded in a narrow channel. The crowded space, together with possible H-bonding effect and cooperative interaction of metals, is crucial for highly selective catalytic reactions.

Although the role of TPP **2** as a coenzyme in pyruvate decarboxylase was established by Lohmann and Schuster [97] in 1937, the mechanism of thiamine promoted biosynthetic process was unclear, which lasted for a long time. In 1943, Ukai *et al.* [98] reported that thiamine and other thiazolium salts could catalyze benzoin condensation of aldehydes under basic conditions, while Mizuhara *et al.* [99] recognized that in this benzoin reaction the role of thiazolium salt was the same as thiamine in catalyzing biochemical reactions, both involved the formation of an acetyl C1-carbanion intermediate or its equivalent.

A rational mechanism for thiamine catalysis was proposed by Breslow in 1958 (Scheme 8) [100]. He noticed that C2-H on thiazolium ring could undergo fast H-D exchange with deuterium oxide, indicating easy formation of C2-carbanion from thiazolium salt. Based on Lapworth's theory of cyanide catalyzed benzoin reaction [101], Breslow proposed that thiazolino-2-ylidene 4 (originally written as a C2-carbanion), a heterocyclic carbene, was the actual catalyst in thiamine promoted benzoin reactions. First, the addition of *in situ* formed thiazolino-2-ylidene 4 with aldehyde **5a** after 1,2-H shift generates an enaminol intermediate **7**, now known as the Breslow intermediate, which acts as a nucleophile to attack another aldehyde molecule. Then, the newly formed intermediate **8** provides a benzoin product **9** and regenerates

Figure 6 Structure of vitamin B_1 (thiamine) and thiamine pyrophosphate (TPP).

Figure 7 Structures of thiamine-dependent enzymes: (a) transketolase; (b) pyruvate decarboxylase (color online).

Scheme 8 Mechanism of thiamine catalysis proposed by Breslow.

the carbene catalyst. Breslow's proposal that thiazolium salts served as carbene precursors to promote transformations without the need of complex enzyme proteins indicated the feasibility of small molecules to mimic thiamine as a catalyst.

3.1.2 N-heterocyclic carbene

Carbenes are neutral species with a divalent carbon atom. Due to their incomplete electron octet, carbenes are often regarded as highly reactive species in organic chemistry, and could not be isolated until the late 1980s and early 1990s when Bertrand *et al.* [102] and Arduengo *et al.* [103] respectively reported the preparation of stable carbenes, phosphinocarbene **10** and *N*,*N*⁻di(adamantyl)imidazolin-2-

ylidene (IAd, **11**) (Figure 8). Since then, the development of *N*-heterocyclic carbene (NHC) catalysis in organic synthesis has been widely explored.

Early reports of vitamin B₁-based biomimetic catalysis were dominated by the thiazolium derivatives, while with the development in this field imidazolium and triazolium derived NHC catalysts became popular (Figure 9). The origin of vitamin B₁-based biomimetic asymmetric catalysis could be dated back to 1966 when Sheehan and Hunneman [104] investigated the asymmetric benzoin reaction by utilizing chiral thiazolium salts as NHC precursors. After that, a variety of chiral thiazolium-based NHC catalysts were synthesized with the introduction of chiral centers on either Nalkyl substituents or the thiazolium backbones (Scheme 9a). Similarly, chiral amines were the main chirality sources for imidazole or imidazoline-based NHC catalysts (Scheme 9b). As first reported by Enders and coworkers [105], chiral triazolium-based NHC catalysts became popular in catalytic asymmetric transformations because of their wide variety and easy access. Versatile chiral triazoliums were prepared from aminoalcohols, natural amino acids, and lactams, etc. (Scheme 9c, d). Overall, the vast number of chiral thiazolium-, imidazolium- and triazolium-based catalysts constituted an inclusive toolbox for asymmetric NHC catalysis [20].

3.2 NHC catalysis via Breslow intermediate

The addition of NHC to aldehyde generates the corresponding Breslow intermediate, which serves as a nucleophile via the umpolung of aldehyde. The Breslow intermediate is very reactive, and early research on the characterization of it encountered difficulties. Berkessel and Teles *et al.* [106] reported a keto tautomer of the Breslow intermediate (**32**), and Rovis *et al.* [107] reported its azaanalogues (*e.g.*, **33**) and measured their oxidation potentials (Figure 10). The *O*-methylated Breslow intermediates (*e.g.*, **34**) and their nucleophilicity were investigated by Maji and Mayr (Figure 10) [108]. It was until very recently that Berkessel and coworkers [109] fulfilled the characterization of the solution and X-ray crystal structure of Breslow inter-

Figure 8 Structures of stable carbenes.

Figure 9 General types of carbene catalysts.

Scheme 9 Typical synthetic procedures of chiral NHC precursors.

mediate (35) and confirmed its role as an acyl anion equivalent in catalytic reactions (Figure 10).

3.2.1 Benzoin reaction

Among NHC-catalyzed various transformations, the benzoin reaction is widely investigated, and asymmetric benzoin reaction has become a benchmark reaction to test the activities of novel chiral NHC catalysts. The results of several representative NHC catalysts on asymmetric benzoin reactions are summarized in Scheme 10 [104,110]. Firstly reported by Sheehan and Hunneman [104], chiral thiazolium 36 worked as the preNHC catalyst to give the benzoin product 9 with 22% ee [110a]. Bicyclic thiazolium salt 37 by Leeper and coworkers [110b] could elevate the benzoin reaction efficiency but still with low ee values. A breakthrough of this asymmetric reaction was realized by Enders and coworkers who employed triazolium **39** as the NHC precursor to deliver the corresponding product in 83% yield with 90% ee [110c]. The bifunctional NHC 31a with a free hydroxyl group, developed by Ye's group [111], promoted the benzoin reaction with 99% ee. The bifunctional NHC 40 bearing a thiourea moiety was employed by Waser and coworkers [110e].

Asymmetric intramolecular benzoin reactions *via* NHC catalysis also have been well established. Tetracyclic triazolium **43** were evaluated by Enders and coworkers [112] to achieve intramolecular benzoin reactions with moderate to good enantioselectivities (Scheme 11a). Suzuki and coworkers [113] disclosed that an aminoindanol-derived NHC precursor **44**, first reported by Rovis *et al.* [114], showed

Figure 10 Structure of the Breslow intermediate and its analogues.

Scheme 10 Representative NHCs in asymmetric benzoin reactions.

excellent enantioinduction effect in most cases (Scheme 11b). You and Jia [115] developed a method for the asymmetric synthesis of dihydroisoquinolones *via* intramolecular benzoin reactions, with the employment of a camphorderived preNHC **45** (Scheme 11c).

3.2.2 Aza-benzoin reaction

An asymmetric aza-benzoin reaction was disclosed by Miller and coworkers [116] in 2005 (Scheme 12a). A chiral peptide thiazolium **48** was utilized to deliver the corresponding α aminoketones in good yields with up to 87% ee. Rovis and DiRocco [117] demonstrated the highly enantioselective reactions between aliphatic aldehydes and *N*-Boc aldimines by using an aminoindanol-based NHC precursor **25a** (Scheme 12b). Reactions of straight-chain aldehydes proceeded well, while branched aldehydes gave the products with excellent enantioselectivities but in low yields.

Taking into account the potential H-bonding effect in enzyme catalysis, Ye and coworkers [118] designed a novel type of bifunctional carbene catalyst (**31**) with an H-bond donor, derived from L-pyroglutamic acid [20h]. A highly enantioselective aza-benzoin reaction of enals with ketimines was established with the employment of hydroxycarbene catalyst **31b** (Scheme 13). In comparison, *t*-butyldimethylsilyl (TBS) protected NHC **30a** with the same backbone was proved to be ineffective, indicating the significance of hydrogen-bonding effect between the catalyst and imine substrate. It is interesting that possible competing

Scheme 11 Selected examples of intramolecular benzoin reactions.

reactions *via* either enolate or homoenolate intermediates were suppressed.

3.2.3 Stetter reaction

In 1976, Stetter [119] reported a thiazolium catalyzed 1,4addition of aldehydes to Michael acceptors to access 1,4difunctionalized molecules, which provided a new synthetic approach for NHC catalysis. Such kind of transformation was named after Stetter. Enders and coworkers [120] first realized the enantioselective intermolecular Stetter reaction of *n*-butanal and chalcone with moderate enantioselectivity by utilizing a chiral thiazolium catalyst. An improved ee value was obtained when they introduced a bicyclic triazolium carbene precursor **57** for the reaction of aromatic aldehyde with chalcone **56** (Scheme 14a) [121]. The Rovis's group [122] reported the Stetter reactions of glyoxamide **59** with α , β -unsaturated esters **60** in good yields with excellent enantioselectivities (Scheme 14b).

Intramolecular Stetter reaction *via* NHC catalysis was disclosed by Ciganek [123] in 1995. Enders and coworkers [124] first reported an enantioselective variant of such kind of reaction. Triazolium preNHC **38** was utilized to deliver 4-chromanones in moderate to good yields with 41%–74% ee. Since then, asymmetric Stetter reaction has become an arena with the introduction of novel NHC catalysts, and substrates bearing different linkers between the aldehyde group and versatile Michael acceptors. Selected examples of NHC catalysts for enantioselective intramolecular Stetter reactions were listed in Scheme 15 [114,125].

Scheme 12 Enantioselective intramolecular aza-benzoin reaction by Miller *et al.* [116] and Rovis *et al.* [117].

Scheme 13 Enantioselective aza-benzoin reaction of enals with ketimines *via* bifunctional NHC catalysis.

Scheme 14 Enantioselective intermolecular Stetter reaction by Enders *et al.* [121] and Rovis *et al.* [122].

3.2.4 Hydroacylation reaction

While the Stetter reaction generally refers to acylation of activated alkene that is conjugated to an electron-withdrawing group, She and coworkers [126] developed an NHC catalyzed direct hydroacylation of enol ethers generated *in situ* from tethered alkyl tosylates. Glorius and coworkers [127] disclosed the enantioselective intramolecular hydroacylation of unactivated alkenes (Scheme 16). A morpholine-based bicyclic carbene precursor **69** was employed to give the corresponding chromanones **70** in good yields with excellent enantioselectivities. Soon after, they accomplished the enantioselective intermolecular hydroacylation of cyclopropenes **71** with the use of an *N*-(2,6-dimethoxyphenyl) substituted preNHC **72**, affording the products **73** with high levels of stereocontrol [128].

3.2.5 Umpolung of aldimine

Aldimines often serve as good electrophiles in the field of NHC catalysis [129]. During the research of aldimines involved cycloaddition and aza-benzoin reactions, adducts of NHC catalysts with aldimines were detected by several groups [117,130], possessing a structure similar to the Breslow intermediate (e.g., 77). From another perspective, by using this kind of intermediate to realize the umpolung of aldimines seems to be an interesting topic. In 2017, Biju et al. and Suresh et al. [131], respectively reported the intramolecular aza-Stetter reaction via NHC catalysis, affording the corresponding substituted indole products in moderate to good yields. In these two examples, umpolung of the aldimine to attack the Michael acceptor is the key step. Two years later, Lupton and coworkers [132] demonstrated an enantioselective intermolecular aza-Stetter reaction by utilizing a morpholine-based NHC catalyst 76, giving the desired dihydrocoumarins 78 with excellent levels of stereocontrol (Scheme 17a). Almost at the same time, Biju et al. [133] disclosed an NHC catalyzed highly enantioselective cycloaddition of bisimine 79, providing an approach to access dihydroquinoxalines 81 (Scheme 17b). Density functional theory (DFT) calculations revealed that the initially generated aza-Breslow intermediate was stabilized by the hydroxy group of the substrate due to the hydrogen-bonding effect.

3.3 NHC catalysis via acylazolium intermediate

The addition of NHC to carboxylic acid derivatives or the oxidation of Breslow intermediate would form an acylazolium intermediate **84**, which is of strong electrophilicity (Scheme 18). By utilizing transesterification reaction *via* acylazolium intermediate, Suzuki and coworkers [134] fulfilled asymmetric transformations of vinyl acetate **85a** with secondary alcohols. Kinetic resolution of racemic alcohols was initially realized but with comparatively low enantioselectivities (Scheme 19a). Better results were achieved by Maruoka and coworkers [135] when a bulky vinyl ester was used (Scheme 19b).

The kinetic resolution of racemic 1,2-diol **89** was demonstrated by Yamada, Takasu and coworkers [136] *via* an NHC catalyzed redox esterification reaction (Scheme 20).

Scheme 15 Representative chiral NHCs for intramolecular Stetter reaction.

Scheme 16 Enantioselective hydroacylation reactions of alkene by Glorius *et al.* [127].

Aldehydes bearing a leaving group (82a) at the α -position were selected as the substrate to generate acylazolium intermediate *via* internal oxidation. In this study, a series of aminoindanol-derived NHC catalysts with the introduction of functional groups, such as bromo and nitro groups, on the indane-ring were reported, which presented opportunities for further transformations to increase the diversity of NHC catalysts to a great extent.

3.4 NHC catalysis via azolium enolate intermediate

Azolium enolate (92) is an important intermediate in NHC

(a) Lupton 2019

Scheme 17 Enantioselective NHC catalysis for umpolung of aldimine.

Scheme 18 Generation of acylazolium intermediate.

catalysis to achieve a-functionalization or serve as C2 synthon in [2+n] cycloaddition reactions. A variety of substrates could be used to generate NHC-bounded enolate intermediate, such as ketenes, acyl fluorides, anhydrides and other aliphatic acylazolium precursors (Scheme 21). In 2006, Bode and coworkers [137] presented an NHC catalyzed enantioselective [2+4] cycloaddition reaction of enals with unsaturated imines, giving the corresponding dihydropyridinones in good yields with excellent diastereo- and enantioselectivities (Scheme 22). Mechanistically, addition of NHC to the enal substrate generates a vinyl Breslow intermediate, which undergoes fast β -protonation to form the key enolate intermediate. In the same year, they reported a highly enantioselective oxodiene Diels-Alder reaction via NHC catalysis with α -chloroaldehyde 96 as the azolium enolate precursor (Scheme 22) [138]. Noteworthy was that a very low catalyst loading (0.5 mol%) was sufficient for excellent stereocontrol.

In 2008, Ye and Smith's groups [139] independently reported the asymmetric Staudinger reactions *via* NHC cata-

Scheme 21 Generation of azolium enolate intermediate.

Scheme 22 Enantioselective [2+4] cycloaddition reactions of unsaturated imines/ketones by Bode *et al.* [137,138].

lysis (Scheme 23). In Ye's work, L-pyroglutamic acid derived carbene catalyst 30a was used to deliver β -lactams in

good yields with moderate to good diastereoselectivities and excellent enantioselectivities (Scheme 23a). Two possible catalytic cycles were proposed. One initiated from the addition of carbene to ketene with the generation of an enolate intermediate, while the other started from the NHC-imine adduct, which was isolated from the reaction. Smith *et al.* employed an aminoindanol-based preNHC **25d** as the catalyst and the reaction proceeded well to obtain the β -lactams in good yields, with moderate to good enantioselectivities (Scheme 23b).

In 2012, Chi and coworkers [140] demonstrated the use of stable aliphatic carboxylic esters as azolium enolate precursors to accomplish an asymmetric azadiene Diels-Alder reaction, with a bicyclic carbene as the catalyst (Scheme 24).

Arylacetic esters **104** and aryl substituted unsaturated imines **105** were tolerable substrates to deliver the corresponding dihydropyridones **106** in high yields, with good stereoselectivities. In the carboxylic ester, electron-deficient aryl phenoxide served as a good leaving group after addition of carbene catalyst, generating the key azolium enolate intermediate after deprotonation.

3.5 NHC catalysis via homoenolate intermediate

The polarity of aldehyde could be changed *via* its interaction with carbene catalyst, generating an acylanion equivalent to react in an a¹ to d¹ umpolung. When enals **53** were employed as the substrate, the corresponding vinyl Breslow intermediate **107** would be formed. In 2004, Glorius and Bode's groups [141] independently demonstrated that extended Breslow intermediate selectively reacted with carbonyl compounds at the β -position *via* an a³ to d³ umpolung, and these elegant seminal reports opened a new chapter of NHC catalysis. The extended Breslow intermediate is often viewed as a homoenolate equivalent **108** (Scheme 25) to accomplish β -functionalization, or as a C3 synthon to participate in [3+*n*] cycloaddition reactions [142].

Bode and coworkers [143] disclosed a highly enantioselective cascade annulation of enals 53 with 4-oxoenoates 109 by employing the aminoindanol-derived carbene precursor 25e, affording substituted *cis*-cyclopentenes 111 in moderate to good yields, with excellent diastereo- and enantioselectivities (Scheme 26a). A bicyclic lactone 110 was initially formed, which released a CO_2 to deliver the corresponding cyclopentenes. Similar to Bode's work, Scheidt and coworkers [144] developed a novel concept of dual carbene/Lewis acid catalysis to realize the asymmetric annulation of enals 53 with chalcones 56, providing *cis*-cyclopentenes 112 with high levels of stereocontrol *via* the employment of a Lewis acid, titanium isopropoxide, as the cocatalyst (Scheme 26b).

Asymmetric [3+2] annulations of enals 53 *via* homoenolate intermediate with isatins 113 were reported by Ye

Scheme 23 Asymmetric [2+2] cycloaddition of ketenes with aldimines *via* NHC catalysis.

Scheme 24 Asymmetric azadiene Diels-Alder reaction of aliphatic carboxylic esters.

Scheme 25 Generation of homoenolate intermediate.

and coworkers (Scheme 27) [145]. Bifunctional carbene catalyst **31c** with a hydrogen-bond donor was efficient to deliver the desired spirolactones **114** in excellent yields and stereoselectivities. As a comparison, TBS-protected carbene catalysts **30a/b** were ineffective for this annulation reaction, which indicated the special properties of bifunctional NHC catalysts. A possible transition-state (**TS-A**) was proposed to elucidate the enantioselectivity. The H-bonding effect enhances the reactivity and induces the addition of homoenolate to the *Si* face of isatin.

A novel ferrocene-based planar chiral carbene catalyst **116** was reported by Scheidt and coworkers [146]. In the synthetic process, a chiral aminoalcohol moiety was introduced

Scheme 26 NHC catalyzed cascade annulation of enals with unsaturated ketones.

Scheme 27 Comparison of normal and bifunctional carbones in [3+2] annulations.

for fast resolution *via* column chromatography, allowing for scalable preparation. Application of this planar catalyst **116** was demonstrated to promote asymmetric [3+2] annulations of enal **53a** with α -ketoester **115** (Scheme 28). The corresponding γ -lactone **117** could be afforded in 62% yield with 70% ee (*cis*) and 50% ee (*trans*), but the diastereoselectivity was only 1:1. Additionally, this kind of novel carbene was good ligand for transition-metal catalyzed asymmetric transformations.

In 2008, Scheidt *et al.* [147] disclosed a carbene catalyzed enantioselective [3+3] cycloaddition of enals **53** with nitrones **118** (Scheme 29). Nucleophilic addition of NHC-bound homoenolate intermediate to the 1,3-dipole followed

Scheme 28 Enantioselective [3+2] annulation of enal with ketoester *via* ferrocene-based planar chiral carbene catalysis.

by intramolecular lactonization afforded the heterocyclic compounds **119**, which underwent a subsequent ring-opening process *via* alcoholysis. Both β -alkyl and β -aryl substituted enals were well tolerated to give the corresponding linear esters **120** in good yields, with high stereroselectivities.

Medium-sized ring could also be accessed via NHC catalysis. In 2013, Scheidt and Ye's groups [148] independently disclosed the enantioselective [3+4] annulations of enals with o-quinone methides (o-QMs) to furnish ɛ-lactone products (Scheme 30). In Scheidt's work (Scheme 30a), the reactive o-QMs were generated in situ from silvl protected precursors 121 through a desilylation/elimination process, while Ye and coworkers directly used dioxolane-fused o-QMs 123 as the substrate (Scheme 30b). Mechanistically, carbene adds to enal to form a vinyl Breslow intermediate, which undergoes a subsequent Michael addition to o-QM to give a phenoxide intermediate. Further intramolecular lactonization affords the final product and releases the carbene catalyst. The rearomatization process is proposed to be a driving force and also a key step to suppress the possible competing [3+2] annulations.

Enals were not the only precursor of homoenolate in carbene catalysis. Bode *et al.* [149] reported that α' -hydroxyenones **125** were feasible surrogates for enals to undergo versatile annulation reactions *via* NHC-bound homoenolate intermediate. However, steric substitution of the substrate restricted its application in asymmetric catalysis with the employment of a bulky chiral carbene catalyst **127** (Scheme **31a**). Chi and coworkers [150] demonstrated that saturated carboxylic esters were efficient precursors of homoenolate intermediate. Cascade annulations of aliphatic esters **129** with chalcones **56** *via* NHC catalysis furnished the corresponding cyclopentenes **112** in good yields, with excellent stereoselectivities (Scheme 31b). The homoenolate intermediate was proposed to be generated after β -proton shift to the azolium enolate oxygen.

3.6 NHC catalysis *via* α,β-unsaturated acylazolium intermediate

Similar to the Breslow intermediate, the α,β -unsaturated

Scheme 29 Enantioselective [3+3] cycloaddition of enals with nitrones.

Scheme 30 Enantioselective [3+4] annulation *via* homoenolate intermediate.

Scheme 31 α '-Hydroxyenone and aliphatic ester as homoenolate precursors in NHC catalysis.

acylazolium is an important intermediate in biochemical transformations, serving as a potential biselectrophile. In efforts towards biosynthesis of clavulanic acid **135** (Scheme

32), a potent β -lactamase inhibitor, Townsend and coworkers [151] revealed that TPP-derived α,β -unsaturated acylazolium **134** was proved to be a key intermediate, which promoted the fast development of such intermediate in the field of thiamine biomimetic catalysis. A variety of substrates were demonstrated for the generation of α,β -unsaturated acylazolium intermediate (Scheme 33).

Zeitler reported the carbene catalyzed esterification of ynals with alcohols, which involved the formation of α,β unsaturated acylazolium via β-protonation of alkynyl Breslow intermediate [152]. Later, Bode et al. [153] disclosed the asymmetric β -addition reactions of ynals 136 with Kojic acids 140 (Scheme 34a). Both aromatic and aliphatic ynals were tolerated to furnish the desired acvclic esters 141 in good yields, with excellent enantioselectivities. Xiao and colleagues [154] reported the enantioselective [3+3] annulations of ynals with 1,3-dicarbonyl compounds (Scheme 34b). The corresponding 3,4-dihydropyranones 145 were afforded stereoselectively. Compared with the aromatic ynals, the alkyl substituted ones provided the products with a slightly decreased enantioselectivity. Interestingly, both of the two enantioselective reactions were free of base, possibly due to the easy generation of carbene catalyst from its precursor.

Lupton *et al.* [155] demonstrated the use of unsaturated acyl fluorides **146** as α,β -unsaturated acylazolium precursors. A highly enantioselective Ireland-Coates-Claisen rearrangement of unsaturated acyl fluorides **146** with strained silylated cyclopropanes **147** was achieved, giving the functionalized bicyclic β -lactones **149** in moderate to good yields (Scheme 35). The addition of NHC to unsaturated acyl fluoride generated the α,β -unsaturated acylazolium intermediate, and a fluoride anion to promote the desilylation, which was helpful for the subsequent ringopening of strained cyclopropanes *via* a retro-aldol process. Both β -alkenyl and β -alkyl substituted unsaturated acyl fluorides were tolerable, albeit alkyl substituted β -lactones being afforded in slightly decreased yields and enantioselectivities.

In 2011, Ye and colleagues [156] introduced α -bromo enals **137** as effective α,β -unsaturated acylazolium precursors. Enantioselective [3+3] annulations of α -bromo enals with 1,3-dicarbonyl compounds were reported to access 3,4dihydropyranones in high efficiency (Scheme 36). In this reaction, addition of carbene to α -bromo enal and subsequent debromination generated the corresponding α,β -unsaturated acylazolium intermediate. Noteworthy was that L-pyroglutamic acid derived carbene catalysts bearing a free or silyl protected hydroxy group furnished the cycloadducts with opposite configurations, respectively. The existence of hydrogen-bonding effect between the α,β -unsaturated acylazolium intermediate and carbonyl substrate, or not, was accountable for the differentiation of stereoselectivity.

Scheme 32 Biosynthesis of clavulanic acid.

Scheme 33 Generation of α,β -unsaturated acylazolium intermediate.

Scheme 34 Enantioselective addition reactions of ynals *via* NHC catalysis.

Electron-deficient unsaturated esters **150** were employed by Chi and coworkers [157] to participate in carbene catalyzed asymmetric annulations with ketimines **151** (Scheme 37). The key α , β -unsaturated acylazolium intermediate was formed upon carbene addition to the ester and elimination of the substituted phenoxide. Ketimines with either electron-

Scheme 35 Enantioselective Ireland–Coates–Claisen rearrangement of unsaturated acyl fluorides with silylated cyclopropanes.

Scheme 36 Enantioselective [3+3] annulation of α -bromoenals with 1,3dicarbonyl compounds.

withdrawing or -donating groups on the aryl ring were well tolerated to give the dihydropyridones in high yields, with excellent enantioselectivities. A less bulky carbene precursor 154 was used for the reactions of β , β -disubstituted unsaturated esters 153, and the desired products 155 with a quaternary stereocenter were afforded in good yields with high ee values.

As discussed before, addition of carbene to enal **53** would generate a vinyl Breslow intermediate **107**, a homoenolate equivalent. Studer and coworkers [158] reported that oxidation of the extended Breslow intermediate with external oxidant **156** gave access to the α,β -unsaturated acylazolium intermediate. [3+3] Cycloaddition reactions of enals with 1,3-dicarbonyl compounds *via* oxidative NHC catalysis were disclosed by Studer *et al.* [159]. An asymmetric variant of this annulation reaction was demonstrated by You and colleagues [160] with the employment of the camphor-derived carbene catalyst **45** (Scheme 38). A series of 3,4-dihydropyranones **145** were obtained in moderate to good yields, with high enantioselectivities.

Carboxylic acids are abundant, low-cost and readily

Scheme 37 Enantioselective [3+3] annulation of α,β -unsaturated ester with ketimines.

available compounds. The direct use of carboxylic acids, without the preparation and separation of their derivatives, in carbene catalysis is of great value. Ye and coworkers [161] reported an interesting asymmetric [2+3] annulation reaction with the employment of α,β -unsaturated carboxylic acids 157 as the starting material (Scheme 39). A two-step one-pot process was involved. Mixed anhydride was initially formed from acids in the presence of base and acyl chloride. Then, carbene addition to the mixed anhydride after elimination generated the α,β -unsaturated acylazolium intermediate. Deprotonation of α-amino acetophenone 158 formed an enolate, which underwent Michael addition to the a, \beta-unsaturated acylazolium. Subsequent lactamization afforded the desired γ -lactam 159 and released the carbene catalyst. Curiously, fused lactones instead of γ -lactams were obtained by Chi et al. [162] when they conducted the reactions of enals with alkyl substituted α -amino ketones via oxidative NHC catalysis.

3.7 NHC catalysis via azolium dienolate intermediate

Deprotonation of β -alkyl substituted α , β -unsaturated acylazolium would afford a nucleophilic azolium dienolate intermediate to realize γ -functionalization (Scheme 40). Ye and coworkers [163] demonstrated the carbene catalyzed asymmetric [4+2] annulations of unsaturated acyl chlorides 165 with activated ketones 166 to furnish a series of δ lactones 169 bearing a tetrasubstituted stereocenter in good yields, with good enantioselectivities, which involved the formation of a NHC-bound dienolate intermediate (Scheme 41a). Shortly afterward, Chi *et al.* [164] employed the strategy of oxidative carbene catalysis to complete cycloaddition reactions of β -alkyl enals 170 with trifluoromethyl ketones 166 (Scheme 41b). The addition of Sc/ Mg Lewis acids as cocatalysts was crucial for high levels of enantioinduction.

Ye and coworkers [165] reported that enals bearing a γ -

Scheme 38 Asymmetric [3+3] annulation of enals with 1,3-dicarbonyl compounds *via* oxidative NHC catalysis.

Scheme 39 Asymmetric annulation of α,β -unsaturated carboxylic acid with α -amino acetophenone.

Scheme 40 Generation of azolium dienolate intermediate.

leaving group could be employed as efficient dienolate precursors. The highly enantioselective [4+2] annulations of γ -oxidized enals **171** with azodicarboxylates **172** were developed, representing a good example of asymmetric formal γ -amination (Scheme 42). Both γ -aryl and γ -alkyl substituted enals were tolerable to give the corresponding dihydropyridazinones **173** in good yields with excellent enantioselectivities. Valuable γ -amino acids (*e.g.*, **174**) could be easily accessed from the cycloadducts without apparent erosion of the enantioselectivity.

Scheme 41 Enantioselective [4+2] annulation of activated ketones *via* NHC catalysis.

Small strained-rings are widely utilized in organic synthesis due to their unique properties, while the direct activation of small rings *via* carbene catalysis has not been established. To address this issue, Chi and coworkers [166] selected cyclobutanone **175** as the substrate, and fulfilled its activation through carbene addition and subsequent ring-opening process, generating an azolium dienolate intermediate.

Then, the [4+2] cycloaddition reaction of cyclobutenones with either saccharin- or isatin-derived imines under carbene catalysis proceeded efficiently (Scheme 43). Aminoindanolbased carbene catalysts **25e/g** were proved to be effective to furnish lactam products **177** with excellent enantioselectivities and in good yields.

3.8 NHC catalysis via $\alpha,\beta-\gamma,\delta$ -bisunsaturated acyl azolium intermediate

Introduction of additional conjugated C=C bonds to the carbonyl substrates provides possibilities for carbene catalyzed remote-site activation (Scheme 44). Chi and coworkers [167] first disclosed the generation of α , β - γ , δ -bisunsaturated acyl azolium intermediate *via* oxidative carbene catalysis with the employment of α , β - γ , δ -bisunsaturated aldehyde **178** as the substrate. The addition of 1,3-dicarbonyl compounds to this type of intermediate occurred selectively at the δ -position. A new benzene ring was formed after cascade annulation and decarboxylation steps. Further application of this strategy by Zhu *et al.* [168] fulfilled the construction of axially chiral biaryl compounds (Scheme 45). A series of *ortho*-substituted benzyl ketones **181** and bisunsaturated aldehydes **178** were selected as the substrates, affording the

Scheme 42 Enantioselective [4+2] annulations of γ -oxidized enals with azodicarboxylates.

Scheme 43 Enantioselective [4+2] annulation of cyclobutenones with imines.

Scheme 44 Generation of $\alpha,\beta-\gamma,\delta$ -bisunsaturated acyl azolium intermediate.

corresponding atropisomeric biaryls **184** in good yields with excellent enantioselectivities. The formation of axial chirality was proposed through a formal central-to-axial chirality conversion.

Lupton and coworkers [169] presented another protocol for δ -carbon activation *via* NHC catalysis. Substituted α,β - γ , δ -bisunsaturated acyl fluorides **186** were utilized as the precursor of α,β - γ,δ -bisunsaturated acyl azolium intermediate. Annulation reactions of the substrates with TMS enol ether of 1,3-dicarbonyl compounds (**185**) proceeded efficiently to deliver the corresponding fused- β -lactones **188**

Scheme 45 Asymmetric cascade reaction of $\alpha,\beta-\gamma,\delta$ -bisunsaturated aldehyde with ketone.

in moderate to good yields, with high levels of stereocontrol (>20:1 dr for all cases, up to >98% ee) (Scheme 46).

3.9 NHC catalysis via p-quinodimethane intermediate

Activation of remote positions of carbonyl compounds *via* carbene catalysis is attractive for organic chemists, but the enantioselective control at remote site is challenging due to its long distance from the chiral catalyst backbone. Very recently, Ye's group [170] demonstrated a novel protocol for carbene catalyzed ε -functionalization transformation. ε -Umpolung of aldehyde *via* a *p*-quinodimethane intermediate (*p*-QDM, **189**) and its nucleophilic addition to ketones were reported, giving the corresponding tertiary alcohols in good yields under mild conditions (Scheme 47). An attempt for asymmetric catalysis by using chiral triazolium **25e** led to the product **190** in 60% yields with 11% ee, indicating the challenge of enantioinduction at the remote site.

3.10 Cooperative NHC/photo catalysis

Photocatalysis has emerged as an efficient tool in synthetic chemistry for easy generation of highly reactive radical intermediate. Cooperative NHC/photo catalysis provides an important platform for interesting chemical transformations. In 2012, Rovis and coworkers [171] first demonstrated this protocol, realizing enantioselective aza-benzoin reactions of *N*-aryl tetrahydroisoquinolines **191** by using an aminoindanolbased NHC precursor **25h** as the catalyst and Ru(bpy)₃Cl₂ as

Scheme 46 Asymmetric cascade reaction of $\alpha,\beta-\gamma,\delta$ -bisunsaturated acyl fluorides with TMS enol ethers.

Scheme 47 Primitive enantioselective ε-addition of 4-(chloromethyl)benzaldehyde to ketone.

the photocatalyst (Scheme 48). The corresponding α -amino ketones **196** could be afforded in good yields with excellent enantioselectivities. Mechanistically, Ru(III) is generated upon oxidation of photoexcited Ru(II)* by a mild oxidant *meta*-dinitrobenzene (*m*-DNB). Tertiary amine is then oxidized by Ru(III) into a radical cation, which further undergoes 1,2-H shift and deprotonation to afford an iminium ion **194**. Addition of Breslow intermediate **193** to iminium ion followed by elimination affords the final product **196** and regenerates the carbene catalyst **192**.

Scheidt and coworkers [172] disclosed a radical alkylation reaction of carboxylic acid derivatives with the strategy of dual carbene/photoredox catalysis. 4-Alkyl substituted Hantzsch ester was proved to be an effective alkyl radical precursor and its reaction with acyl imidazole proceeded efficiently by using a simple triazolium as the catalyst and an iridium complex as the photocatalyst under blue LED irradiation. An example of enantioselective catalysis was presented with the use of an aminoindanol-derived carbene catalyst **25d**, affording the corresponding ketone product **200**

Scheme 48 Enantioselective aza-benzoin reaction *via* dual NHC/photo-redox catalysis and the proposed catalytic cycle.

with 32% ee (Scheme 49). Similar to Scheidt's work, Chi *et al.* [173] realized an alkylation reaction of esters with the same kind of radical precursor. Interestingly, this visible-light promoted reaction proceeded well without the use of any photosensitizer.

Very recently, Studer and coworkers [174] reported the fluoroaroylation of benzofurans *via* cooperative carbene/ photoredox catalysis with aroyl fluorides serving as bifunctional agents. The desired functionalized 2,3-dihy-drobenzofurans could be afforded in good yields with good regio- and diastereoselectivities. An asymmetric variant was demonstrated to furnish the product **203** in 53% yield, 30% ee and >20:1 dr, with the employment of morpholine-based NHC catalyst **187** and the photosensitizer **199** (Scheme 50).

Remote radical reaction *via* cooperative NHC/photo catalysis was also developed. In 2016, Sun's group [175] reported one example of visible light induced NHC catalyzed γ -dichloromethylenation with trichloromethyl radical. Later, Ye and coworkers [176] disclosed an interesting γ - and ε -alkylation of γ -oxidized enals by combination of carbene catalysis and photocatalysis. Attempt for asymmetric catalysis was also carried out, furnishing the γ -alkylated product **206** in 57% yield with 29% ee by using morpholine-based carbene catalyst **205** (Scheme 51). Noteworthy was that when γ -vinyl substituted γ -oxidized enals were employed, alkyl radical addition occurred selectively at the ε -position rather than the γ -position as previously observed, implying the involvement of an azolium trienolate intermediate.

3.11 Cooperative NHC/transition-metal catalysis

NHCs are good ligands for transition-metal catalysis and the complexes of metal-NHC are effective catalysts for various organic reactions. However, coordination of NHC with

Scheme 49 Radical alkylation of acyl imidazole *via* cooperative NHC/ photoredox catalysis.

Scheme 50 Fluoroaroylation of benzofurans *via* dual NHC/photoredox catalysis.

Scheme 51 Remote alkylation of γ -oxidized enals *via* dual NHC/photo-redox catalysis.

transition-metal might be detrimental for cooperative catalysis by inhibiting the reactivity of carbene as an organocatalyst. To address this issue, several groups employed an additional ligand for metal catalyst and regulated the steric and electron effects of NHC to alleviate and even avoid its coordination to transition-metal center.

Glorius *et al.* [177] first demonstrated the asymmetric NHC/Pd dual catalysis, realizing [3+4] annulation of enals **53** with vinyl benzoxazinanones **207** to access azepine derivatives **209** with up to 99% ee (Scheme 52). Detailed mechanistic investigation reveals that NHC both serves as an organocatalyst and a ligand to form a Pd/NHC/phosphine complex, and that the phosphine ligand is crucial for this annulation reaction. The asymmetric [5+2] cycloaddition reaction of enals with vinylethylene carbonates *via* cooperative NHC/Pd catalysis has also been developed by

Glorius and coworkers [178].

In 2020, the Glorius's group [179] reported an example of dual NHC/Ir asymmetric catalysis, accomplishing the annulation reaction via NHC-bound enolate intermediate with Ir-allyl complex (Scheme 53). The corresponding lactones and lactams were afforded in good vields, with good diastereoselectivities and excellent enantioselectivities. Soon afterward, Deng and coworkers [180] demonstrated an alternative protocol of NHC/Ir cooperative catalysis to promote regiodivergent [3+2] and [3+3] annulations of enals with allyl indoles, furnishing fused lactams with high levels of stereocontrol. Interestingly, base plays an important role in regulating the regioselectivy of this reaction. Recently, an enantioselective [4+3] annulation of anthranilaldehydes or salicylaldehydes with vinyl aziridines to access benzodiazepinones and benzoxazepinones via cooperative NHC/Ir/ urea catalysis was well developed by Gong, Song and coworkers [181].

A cooperative NHC/Cu catalysis was disclosed by Gong, Song and coworkers [182]. Enantioselective annulation reactions of isatin-derived enals **213** with ethynyl substituted carbonates/benzoxazinanones (**216/214**) proceeded efficiently with the employment of chiral NHC precursor and copper catalyst (Scheme 54). A Cu-NHC complex was identified *via* ESI-MS spectroscopy. The key copperallenylidene intermediate **219** was proposed to be generated after sequential deprotonation and decarboxylation of ethynyl-copper complex. Nucleophilic addition of homoenolate **218** to copperallenylidene **219** formed a C–C bond, followed by intramolecular lactonization/lactamization and protonation to provide the corresponding cycloadduct and release the carbene catalyst.

Just recently, Ye and coworkers [183] demonstrated the compatibility of cooperative NHC and Ni catalysis. Hydroacylation of 1,3-dienes with aldehydes was achieved with water as the sole solvent. Mechanistic studies excluded the common process of Ni-promoted aldehyde-to-alkene hydrogen transfer and thus estimated the dual catalysis mechanism. Soon after, Gong, Song and coworkers [184] disclosed a highly enantioselective β -allylation reaction of isatin-derived enals **213** with vinyl epoxides **222** and allylic carbonates **225** (Scheme 55). The corresponding allylic products could be afforded in good yields, with excellent stereoselectivities. A Ni(0)/Ni(II) catalytic cycle was proposed with Ni-allyl complex as the key intermediate to react with the NHC-bound homoenolate.

Asymmetric relay catalysis of NHC with other transitionmetals, such as Cu [185], and Au [186] was also well established.

3.12 NHC catalysis via other modes

The scope of asymmetric carbene catalysis is not restricted to

Scheme 52 Enantioselective [3+4] annulation of enals with vinyl benzoxazinanones *via* NHC/Pd cocatalysis.

Scheme 53 Asymmetric annulation of enals or α -chloroaldehydes with vinylethylene carbonates *via* dual NHC/Ir catalysis.

carbonyl substrates with the formation of NHC-bound acyl anion or azolium intermediates. Carbene as a Lewis base can also add to Michael acceptor to generate a zwitterionic intermediate, subsequent nucleophilic addition of which to other electrophiles offers approaches for the Morita-Baylis-Hillman (MBH) and Rauhut-Currier (RC) reactions.

In 2007, Ye and colleagues [187] first disclosed the car-

Scheme 55 Enantioselective β -allylation of isatin-derived enals with allylic carbonates and vinyl epoxides *via* dual NHC/Ni catalysis.

bene catalyzed MBH-reactions by employing cyclic enones and *N*-Ts aldimines as the substrates [130b]. An asymmetric variant was reported with the use of bifunctional carbene **31c**, affording the adduct **229** with a promising enantioselectivity (44% ee) (Scheme 56a). Later, a RC-type [4+2] annulation of nitroolefins with cyano-chalcones was reported by the same group [188]. The desired dihydrolpyranes could be obtained in good yields with moderate to good diastereoselectivities. An enantioselective variant was also presented with the employment of bifunctional carbene **31b**, giving the cycloadduct **232** in 24% yield, 5:1 dr and 29% ee (Scheme 56b).

A highly enantioselective RC-reaction *via* carbene catalysis was reported by Lupton and coworkers [189] in 2019. The morpholine-based carbene catalyst **187** with an *N*-(2,6-dimethoxyphenyl) group was effective to promote intramolecular reactions of less electrophilic bis(enoate) **233**, affording lactone products **234** in moderate to good yields with >20:1 dr for all cases and up to 96% ee (Scheme 57). Intermolecular reactions by employing α , β -unsaturated acyl fluorides and TBS protected naphthols *via* a cascade esterification/RC-reaction process were also achieved in an enantioselective manner.

3.13 Summary and perspectives of vitamin B₁-related N-heterocyclic carbene catalysis

The past decades have witnessed the enormous capacity of N-heterocyclic carbenes to mimic vitamin B₁ in catalytic asymmetric transformations. Broad scope of substrates has been well established, ranging from aldehydes to ketenes, carboxylic acids, and their derivatives, etc. Carbene catalysis, with the generation of various nucleophilic and electrophilic intermediates, has accomplished selective functionalization at different position of the substrate. Despite the great advances, defects of carbene catalysis at current stage are also apparent. Carbene catalyst loading is still very high, about 10 mol%-20 mol% for most cases. Enantioselective control of carbene catalyzed radical reactions and remote functionalizations is still challenging. Thus,

Scheme 56 Asymmetric MBH and RC reactions *via* bifunctional NHC catalysis.

Scheme 57 Enantioselective intramolecular R-C reaction of bis(enoate).

the design and application of novel reactive and selective carbene catalysts, especially the bifunctional ones, are highly desirable. Cooperative carbene catalysis with other catalytic strategies, to expand the scope to "inert" substrates, would undoubtedly lead to the discoveries of novel activation modes and interesting chemical transformations.

4 Vitamin B₆-based asymmetric catalysis

4.1 Vitamin B₆-dependent enzymatic transformations

Vitamin B_6 (VB₆), containing pyridoxal (PL), pyridoxamine (PM) and the related phosphorylated derivatives (PLP and PMP), is an essential coenzyme in living organism [190]. The VB₆-dependent enzymes are an enormous family containing hundreds of members (around 4% of the all enzyme activities) [191]. Typically, pyridoxal/pyridoxamine serves as the catalytic active site while proteins provide chiral surrounding for enzymatic reactions, wherein the amino acid residues of the proteins are able to accelerate the rate of biological conversion *via* cooperative catalysis. It is discovered that these enzymes catalyze numerous transformations mainly involving the synthesis and metabolism of amino acids and amines, such as transamination, aldol reaction of glycine, retro aldol reaction of β -hydroxy- α -amino acids, decarboxylation and racemization of α -amino acids, β substitution of serine and derivatives (Figure 11), supplying diversified chiral bio-based amines [192].

Among these VB₆-dependent enzymes, aminotransferases and threonine aldolases were the most investigated ones. In the process of transamination, the 1,3-proton shift of imines **235/237** prompts the amino group transferring from an amino acid toward a keto acid, wherein pyridoxal and pyridoxamine are interconvertible *via* two half-transaminations (Scheme 58) [193,194]. Regarding the threonine aldolase enabled aldol reaction of glycine, instead of 1,3-proton shift, intermediate **238** proceeds addition toward aldehyde to afford β -hydroxy- α -amino acids (Scheme 59) [195]. In these biological transformations, the Lys residue not only pro-

Figure 11 Vitamin B_6 and related enzymatic transformations (color online).

Scheme 58 Biological transamination (color online).

motes the 1,3-proton shift or the electrophilic addition to aldehyde as an intramolecular base but aslo assists the product release *via* forming internal aldimine as well [196]. This cooperative effect of the Lys has been proven by the evidence that changing the lysine with a different amino acid or totally removing it *via* mutagenesis resulted in up to 10^6 -fold deceleration of transamination [197]. Due to the synthetic importance of these products (chiral α -amino acids and β hydroxy- α -amino acids), VB₆-based biomimetic asymmetric catalysis primarily includes the simulation of transaminases and threonine aldolases.

Given the VB₆ possesses powerful catalytic ability and enables a wide range of reactions to deliver chiral amines that have been vastly utilized in pharmaceuticals, fine chemicals as well as materials, the development of VB_6 dependent biomimetic catalysis is of central importance and thus have drawn considerable attention from chemists since 1940s [21,198]. Precedent studies have demonstrated that the 3-OH, 4-CHO/CH₂NH₂, and the pyridine ring of PLP and PMP are indispensable for catalytic function (Figure 12). The 5-phosphate is not catalytically necessary, and it is adjacent to the catalytic center (4-CHO/CH₂NH₂). Accordingly, the 5-position of the pyridine ring is an ideal place to introduce an appropriate moiety to construct chiral biomimetic pyridoxal/pyridoxamine catalysts, which are capable to imitate the corresponding enzymes in varied transformations. In the course of biomimetic catalyst design, it has been found that the functional side chain tethered to the 5-position as well as the electronic property of the pyridine ring impact catalytic activity and selectivity. The side chain is expected to mimick the amino acid residues of enzymes to perform cooperative catalysis.

4.2 Bio-inspired enantioselective reactions enabled by stoichiometric chiral pyridoxamines and pyridoxals

In 1978, Kuzuhara's group [199] reported the first biomimetic asymmetric transamination using stoichiometric chiral pyridoxamine 241 to imitate aminotransferase. Compound 241 acted as amino source to transfer its NH₂ to α -keto acids, delivering the corresponding pyridoxal 242 and enantioenriched a-amino acids. Further studies demonstrated the ratio of Zn²⁺/241 affected the enantioselectivity. Pyridoxamine 241b (1 equiv.) together with and $Zn(ClO_4)_2$ $\cdot 6H_2O(0.5 \text{ equiv.})$ enabled the asymmetric transamination to provide chiral amino acids with up to 96% ee (Scheme 60) [200]. Breslow and his coworkers [201] also investigated stoichiometric bio-inspired transamination of a-keto acids using a series of pyridoxamines with a chiral sulfur-containing side chain. Pyridoxamine 244 delivered optically active α -amino acids with up to 92% ee [201b]. The side arm was assumed to has an analogous cooperative effect as the Lys residue of transaminases, accelerating the process of the

Scheme 59 Biological aldol reaction (color online).

Figure 12 VB₆-based biomimetic catalyst design (color online).

Scheme 60 Asymmetric transamination promoted by pyridoxamines 241 (color online).

transamination (Scheme 61). In addition, chiral pyridoxals **245** (Kuzuhara) [202] and **246** (Breslow) [203] were employed for imitation of biological aldol reaction of glycine, wherein complex **247** consisting of pyridoxal, glycine, and metal was formed initially and then underwent nucleophilic addition to aldehyde to furnish optically active threonine with up to 74% ee and allo-threonine with up to 88% ee, respectively (Scheme 62). Although beyond the scope of this review, the studies of VB₆-related artificial enzymes developed by Breslow are still worth mentioning, which described β -cyclodextrin-derived [204] or chiral-polymer-attached [205] pyridoxamines (**248** and **249**) enabled biomimetic enantioselective transamination (Figure 13).

Scheme 61 Asymmetric transamination promoted by pyridoxamines 243 and 244 (color online).

4.3 Vitamin B₆-based catalytic asymmetric biomimetic transamination

The first chiral pyridoxal/pyridoxamine catalyzed asymmetric transamination was reported by Zhao's group. They found chiral pyridoxal **250** [206] and chiral pyridoxamine **251** [207] were both capable to catalyze asymmetric biomimetic transamination of α -keto acids with diphenylglycine as a sacrificial amine source (Scheme 63). Previous catalytic asymmetric protocols mainly involved artificial enzymes [208] as well as chiral base/acid [209,210] catalyzed asymmetric 1,3-proton shift of Schiff bases. Zhao et al. [211] later discovered axially chiral biaryl pyridoxamine 252a owned the competence to enable highly enantioselective amino transfer reaction, delivering a variety of α -amino acids with excellent activity and enantioselectivity (up to 99% yield and 94% ee) (Scheme 64). Catalyst comparison revealed that the NHMe lateral chain was crucial for the obviously high activity and enantioselectivity. It was supposed to mimick the Lys residue of transaminases to accelerate the asymmetric transamination via cooperative catalysis (Scheme 64 below) [196]. A proposed reaction pathway illustrates this enzymelike process (Scheme 65). Chiral pyridoxamine captured α keto acid to form ketimine 253, which consequently proceeded 1.3-proton shift, promoted by the amine group of the side chain, forming aldimine 255. Under the assistance of the amine side chain, amino acid product was released along with the formation of internal iminium 252a'. Iminium 252a' underwent decarboxylative transamination with diphenylglycine to regenerate pyridoxamine 252a, completing a catalytic cycle. Chiral induction occurs during the step of the asymmetric 1,3-proton shift, forming chiral aldimine 255 from ketimine 253. As delineated in transition state model **259**, the amine fastens the carboxylic group of α -keto acid by acid-base and/or hydrogen bonding interactions and also serves as an intramolecular base to deprotonate the benzylic C-H of ketimine 253 from beneath, producing the deloca-

Scheme 62 Asymmetric aldol reaction promoted by pyridoxals **245** and **246** (color online).

Figure 13 VB₆-based artificial enzymes developed by Breslow (color online).

Scheme 63 Asymmetric transamination of α -keto acids catalyzed by 250/251 (color online).

lized azaallylanion. Conversely, protonation of the azaallylanion occurs from the top, generating (*S*)- α -amino acid from (*R*)-pyridoxamine catalyst **252a**. Altogether, this study not only initiates a new avenue to optically active α -amino acids, but also demonstrates that multiple imitation of enzymes is a promising strategy to develop highly efficient biomimetic catalysts.

Encouraged by the outstanding performance of chiral pyridoxamine **252a** in biomimetic transamination of α -keto acids, Zhao's group [212] recently reported their studies on the stereo-divergent transamination of α -keto amides to peptides (Scheme 66). To address the challenge of low reactivity of α -keto amides, N-quaternized chiral pyridoxamines **260** [213] were designed to make the pyridine ring

Scheme 64 Pyridoxamine 252a enabled catalytic asymmetric transamination of α -keto acids (color online).

Scheme 65 The proposed transamination mechanism and transition state for chiral induction (color online).

more electron-deficient for facilitating deprotonation of the ketimine formed between α -keto amide and pyridoxamine [214]. By this catalyst, a wide array of α -keto amides underwent asymmetric transamination to offer pharmaceutically and biologically crucial peptides with up to 90% yield, 98% ee or 99:1 dr. The peptides could be obtained as diastereomers respectively by using configurationally reverse catalysts. Intriguingly, a successive "condension-transamination" strategy was employed to make hexapep tide **262** from tetrapeptide **261**, the methyl ester of DPP-IV inhibitor Diprotin A [215], exemplifying an efficient approach for peptide extension (Scheme 66).

Scheme 66 Pyridoxamine 260 enabled catalytic asymmetric transamination of α -keto amides (color online).

4.4 Vitamin B₆-based biomimetic asymmetric carbonyl catalysis

As a novel catalysis mode, carbonyl catalysis utilizes an appropriate aldehyde or ketone to catalyze α -C-H functionalization of primary amines without protecting group manipulations towards the NH₂ group, providing a new attractive strategy to make α -substituted chiral amines [216]. Threonine aldolase enabled aldol reaction of glycine actually is a typical biological carbonyl catalysis process [195], wherein pyridoxal 5'-phosphate temporarily protects glycine by forming imine 238 to increase its α -C–H acidity, promoting the succeeding nucleophilic addition to aldehydes (Scheme 59). Inspired by this enzymatic transformation, in 2018, Zhao and his coworkers [217] reported their efforts on VB_6 -based biomimetic carbonyl catalysis (Scheme 67). Chiral pyridoxal 263 has proven highly effective in enantioselective Mannich reaction of glycinate and imines. Under 0.2-1 mol% catalyst loading, a great range of N-diphenylphosphinyl aromatic imines went through asymmetric Mannich reaction with NH₂-unprotected glycinate to deliver structurally attractive and pharmaceutically relevant α,β diamino acid esters with up to 94% yield, 99% ee and >20:1 dr. The reaction proceeds via a mechanistic pathway similar to that of enzymatic aldol of glycine (Scheme 67). Condensation of glycinate with pyridoxal catalyst 263 forms imine 264. Deprotonation of aldimine 264 leads to delocalized carbanion 265 which is stabilized by N-quaternized pyridine [218]. Asymmetric addition of carbanion 266 to Ndiphenylphosphinyl imine followed by the hydrolysis of compound 267 produces chiral α,β -diamino acid ester and regenerates pyridoxal 263. As shown in transition state Ts-**266**, the amide lateral arm participates in activation of N-

Scheme 67 Pyridoxal 263 catalyzed biomimetic asymmetric Mannich reaction and its mechanism (color online).

diphenylphosphinyl imine by double hydrogen bonds. The enzyme-like cooperative catalysis accounts for the astonishingly high activity and stereoselectivity of pyridoxal catalyst **263**.

Taking advantage of carbonyl catalysis strategy [219], Zhao et al. [220] further achieved catalytic asymmetric biomimetic aldol reaction between glycine and trifluoromethyl ketones by employing chiral pyridoxal catalyst 268 (Scheme 68). By using only 0.1 mol% catalyst loading, diverse alkyl trifluoromethyl ketones were effective for this transformation and furnished enantiomerically enriched βtrifluoromethyl-β-hydroxy-α-amino acids (up to 82% yield, 99% ee, and >20:1 dr), which are frequently found in biologically active molecules. The incredible high efficiency of biomimetic catalyst was revealed by the fact that 0.0033 mol% pyridoxal 268 still enabled this aldol reaction to deliver product 269 with 59% yield, 97% ee and 13:1 dr, which has reached (even surpassed) the efficiency of related enzymes. Mechanistic investigation disclosed that N-methylation of the pyridine ring and the N-H group on the side chain combined with the additive Tf₂NH all contributed to the fantastic activity and stereoselectivity of this transformation (Ts-270).

In addition to biomimetic Mannich and aldol reactions, Zhao and his coworkers continuously explored new α -C–H transformations of glycinates. In 2020, they applied chiral pyridoxal **271** into the 1,4-conjugated addition of glycinate

Scheme 68 Pyridoxal 268 catalyzed biomimetic asymmetric aldol reaction (color online).

towards α,β -unsaturated esters, to afford a variety of biologically significant chiral pyroglutamic acid esters with up to 96% yield and 97% ee albeit with low trans/cis ratios caused by rapid epimerization under the basic reaction conditions (Scheme 69) [221]. Surprisingly, N-methyl pyridoxal catalyst was inactive for this reaction, probably because the wellstabilized carbanion was not nucleophilic enough for the addition to α,β -unsaturated esters. Besides the catalyst, additive LiOTf was also crucial for the reaction, which was supposed to activate the α,β -unsaturated ester as well as stabilize the enolated anion (Ts-272). Very recently, they reported asymmetric α-allylation of glycinate with Morita-Baylis-Hillman (MBH) adducts (Scheme 70) [222]. Given the activating site of MBH acetate is relatively far from its reactive center, pyridoxal 273 featured with larger chiral cavity by attaching side chain at C3 position of the naphthyl ring was designed and utilized in this S_N2'-S_N2' transformation. Under carbonyl catalysis strategy, NH2-unprotected glycinate directly engaged α -allylation reaction to deliver enantioenriched glutamic acid esters (up to 86% yield, 97% ee and >20:1 dr). Simple transformations of the α -allylation product 275 furnished biologically active lactam 276 and chiral glutamic acid analogue 277 without any loss of enantiopurity, demonstrating the potential of this protocol in synthetic utilization.

Direct functionalization of inert $C(sp^3)$ –H bond is a fundamental but tremendous challenge for modern organic chemistry [223]. In order to pursue their interest in development of biomimetic carbonyl catalysis, Zhao's group [224] extended the exploration of primary amines from activated glycinates to inert substrates. Primary propargylamines are challenging substrates for direct α -C–H functionalization, due to the very low acidity of the α C–H

Scheme 69 Pyridoxal 271 catalyzed asymmetric 1,4-conjugated addition of glycinate (color online).

Scheme 70 Pyridoxal 273 catalyzed asymmetric α -allylation of glycinate with MBH acetates (color online).

bonds (calculated $pK_a \sim 42.6$). Astonishingly, propargylamines can be greatly activated by chiral pyridoxal catalysts **278** *via* the formation of imines, resulting in dramatic increase of the acidity of the α -C–H bonds by up to 10^{22} times (Scheme 71) [225]. Asymmetric α -addition of propargylamines to alkyl trifluoromethyl ketones produced a broad array of structurally intriguing and medicinally significant chiral β -hydroxy- β -trifluoromethyl propargylamines in high yields (up to 84%) and excellent stereoselectivities (up to 99% ee and >20:1 dr). Undoubtedly, the remarkable cooperative effect of lateral arm was also identified in this reaction. Furthermore, primary benzylamines bearing inert α -C-H bonds (calculated pK_a~42.7) was also targeted for straightforward enantioselective α -addition to aldehydes (Scheme 72) [226]. A new sort of chiral pyridoxal 279 featured with a squaramide side chain. of which the double N-H bonds were proven essential for activity and stereoslectivity, was developed for realizing this challenge transformation. Various synthetically useful syn-\beta-aminoalcohols were delivered from diversified benzylamines and benzaldehydes with up to 92% yield, >20:1 dr and 99% ee. The efficiency of this method was demonstrated by the quick synthesis of AM-8735 (282) [227], a morpholinone inhibitor of MDM2-p53 protein-protein interaction, and antagonist MGluR5 PAM (285) [228], wherein pyridoxal 279 catalyzed asymmetric α addition of benzylamines 280 and 283 to aldehydes were the principal step for these streamlined routes.

4.5 Summary and perspectives of vitamin B₆-based asymmetric catalysis

In short, VB₆-based biomimetic asymmetric chemistry has been developed from stoichiometric simulation into catalytic imitation during the past several decades. A variety of novel and efficient pyridoxal/pyridoxamine catalysts have been invented based on the inspiration of the structures and functions of VB₆-dependent enzymes. These pyridoxals/ pyridoxamines have displayed extraordinary performances in catalytic biomimetic transamination and α -C-H functionalization of primary amines. With an axially chiral biaryl pyridoxamine as the catalyst, biomimetic transamination of α -keto acids and α -keto amides were both successfully achieved, respectively producing various bioactive a-amino acids and peptides with excellent enantiopurities. Enzymatic aldol reaction of glycine brought to carbonyl catalysis, a new catalytic mode for direct α -C-H functionalization of NH₂unprotected primary amines with electrophiles. By utilizing chiral pyridoxals as carbonyl catalysts, the strategy has already been applied to the reactions of glycinates and inert primary amines, *i.e.*, propargylamines and benzylamines, with various electrophiles including aldehydes, imines, trifluoromethyl ketones, α,β -unsaturated esters, and Morita-Baylis-Hillman (MBH) adducts. These studies have exhibited the robust and unique catalytic competence of VB₆ for constructing optically active amine compounds, and would further spur the development of VB₆-based biomimetic catalysts for asymmetric catalysis and organic synthesis. Despite the forementioned achievements, VB₆based biomimetic asymmetric catalysis still remains in its early stage of development and some challenges still await to be addressed, which are (1) transamination of inactivated carbonyl compounds, such as alkyl aldehydes and ketones, (2) direct asymmetric α -C-H functionalization of alkyl

Scheme 71 Pyridoxal 278 catalyzed asymmetric α -addition of propargylamines to alkyl trifluoromethyl ketones (color online).

Scheme 72 Pyridoxal **279** catalyzed asymmetric α-addition of benzylamine to aldehydes (color online).

amines enabled by carbonyl catalysis, (3) further development of more efficient chiral pyridoxamine/pyridoxal catalysts, and (4) biomimetic chemistry based on the simulation of other VB₆-dependent enzymatic transformations, such as decarboxylation of α -amino acids and β substitution of serine and derivatives. It is believed that continuous development of this field will eventually unlock a powerful platform for green synthesis of complicated organic compounds.

5 NAD(P)H-based biomimetic asymmetric catalysis

In the cell, the reduced nicotinamide adenine dinucleotide (NADH) and nicotinamide adenine dinucleotide phosphate (NADPH) are recognized as a couple of crucial enzymes, and over 400 enzyme redox reactions, such as the citric acid cycle, glycolysis, and amino-acid decomposition, depend on the interconversion of NAD(P)H and NAD(P)⁺ (Figure 14a). NADH and NADPH contain the 1,4-dihydropyridine rings, which can be used as the hydrogen sources to reduce unsaturated double bonds owing to its driving force of aromatization (Figure 14b) [22,229,230].

Inspired by the reduction mechanism of NAD(P)H, a series of efficient methods to realize biomimetic asymmetric reductions (BMAR) have been studied intensively, accompanying the development of novel NAD(P)H models. According to the type of the NAD(P)H models, it is divided into the following three aspects: (1) BMAR participated by stoichiometric amount of NAD(P)H models; (2) BMAR catalyzed by achiral NAD(P)H models; (3) BMAR catalyzed by chiral NAD(P)H models (Figure 14c).

5.1 BMAR participated by stoichiometric NAD(P)H models

In earlier studies, some scientists modified niacinamide, the core structure of coenzyme NAD(P)H, to satisfy the fact that the NAD(P)H models could have a drive to restore aromatization similar with the coenzyme NAD(P)H. Thus, the BMAR *via* stoichiometric amount of achiral NAD(P)H model were successfully realized with chiral transfer catalyst (Scheme 73).

5.1.1 Stoichiometric achiral NAD(P)H models

Stoichiometric achiral NAD(P)H models mainly include Hantzsch ester (HEH) **285** and benzothiazoline **286** (Scheme 74). In 1985, Gelbard's group [231] first realized the BMAR of methyl benzoylformate by using stoichiometric HEH **285** as the NAD(P)H model and the chiral shift reagent (+)-Eu(tfc)₃ as the Lewis acid. However, the yield and enantioselectivity of the reduction were not satisfactory. Until 2004, List's group [232] achieved BMAR of α , β -unsaturated aldehyde using the stoichiometric HEH and the chiral amine salt as the catalyst in good yield and enantioselectivity (Scheme 75).

Later, Rueping *et al.* [233] and List *et al.* [234] used the combination of catalytic chiral phosphoric acid (CPA) and HEH **285** to achieve the BMAR of ketoimines respectively, resulting in high activities and enantioselectivities (Scheme 76).

Subsequently, in the presence of HEH, the BMAR of some unsaturated substrates containing C=C, C=O or C=N was achieved with the participation of chiral organic catalysts or

Scheme 74 Stoichiometric achiral NAD(P)H models (color online).

metal complexes. Under mild conditions, a great number of important chiral organic synthetic blocks could be obtained with superior yields and enantioselectivities [235–241].

In addition to the Hantzsch ester **285**, benzothiazoline **286** could also be used as the NAD(P)H model, which converted to the more stable benzothiazole after dehydrogenation. In

Gelbard's work

Scheme 75 BMAR of methyl benzoylformate and α,β -unsaturated aldehyde.

Scheme 76 BMAR of ketoimines by the combination of HEH and CPA.

2009, utilizing benzothiazoline **286** and CPA, Akiyama and coworkers [242] achieved the BMAR of ketoimines with excellent activities and enantioselectivities (Scheme 77). Since then, benzothiazoline **286** was mainly used as a NAD(P)H model in the BMAR of C=N bond.

5.1.2 Stoichiometric chiral NAD(P)H models

Compared with the achiral NAD(P)H model, the BMAR involved the chiral NAD(P)H models could be achieved without additional chiral catalysts or reagents. At present, the stoichiometric chiral NAD(P)H models mainly focused on the chiral niacinamide derivatives. The spatial effect on the molecular structure of the NAD(P)H model is generated by each substituent on its active group dihydropyridine, or through its own specific spatial configuration, to achieve stereoselective reactions. According to the symmetry of the NAD(P)H models, it is divided into the following aspects: (1) C_1 -symmetrical chiral NAD(P)H models.

(1) C_1 -symmetrical chiral NAD(P)H models

The design of the C_1 -symmetrical chiral NAD(P)H models is mainly based on the core skeleton of niacinamide, which can be introduced into chiral groups at the N-1, C-3 or C-4 positions, and designed as different types of stoichiometric chiral NAD(P)H models for BMAR.

As early as 1975, Ohnishi's group [243] first applied the NAD(P)H model **287** containing chiral groups at the C-3 position to the BMAR of ethyl benzoylformate. In the pre-

Scheme 77 BMAR of ketoimines by benzothiazoline 286 and CPA.

sence of stoichiometric Mg(ClO₄)₂, the desired hydrogenated product could be obtained with poor 20% ee. The chiral organometallic NAD(P)H model 288 was designed through introducing a chiral iron-containing complex at the C-3 position of nicotinamide by Davies's group [244]. The reduction of ethyl benzoylformate could achieve excellent enantioselectivity (98% ee) because the hydroxyl and carbonyl group of NAD(P)H model jointly involved in the coordination with the Mg^{2+} cation. Due to the similar structure of sulfinyl groups and amides, Iwata's group [245] described the synthesis of the novel NAD(P)H model 289 and their use in effective BMAR of methyl benzoylformate (75% yield, 97% ee). Inspired by this, Levacher's group [246] prepared the 1,4-dihydroquinolines bearing a chiral sulfinyl group, the novel NAD(P)H model 290, which was applied to the asymmetric reduction of methyl benzoylformate with 70% yield and 95% ee. In 2009, the strongly rigidified β -lactam peptidomimetic NAD(P)H model 291 has been synthesized by Aizpurua's group [247] and used to the BMAR of methyl benzoylformate (>99% yield, 90% ee). The chelation of NAD(P)H model with Mg²⁺ cation to form a sevenmembered ring was found to be the actual reason of the excellent stereodiscrimination (Scheme 78).

Inouye's group [248] attempted to introduce the L-prolinamide at the *N*-1 position of the niacinamide, and successfully synthesized the NAD(P)H model **292**. In the presence of Mg(ClO₄)₂, the chiral alcohol was obtained with 90% ee and 39% yield (Scheme 79).

In order to better control the enantioselectivity of the reaction, a series of NAD(P)H models with a chiral center at the C-4 position were synthesized which had reaction and stereocenters at the same position. Ohno's group [249] improved the stereoselectivity in the process of BMAR of methyl benzoylformate by additional introduction of methyl group at the C-4 position in the NAD(P)H model 293. Subsequently, Vekemans and coworkers [250] replaced the chiral amide group with an achiral N,N-dimethylamide group at the C-3 position. The BMAR of ethyl benzoylformate could get 95% ee at -25 °C which indicated that the C-4substituent played an important role in the control of stereoselectivity. In order that the reaction could proceed smoothly at room temperature, Mikata's group [251] described the more stable quinoline-type NAD(P)H model 295 which had the high enantioselectivity (up to >99% ee). In 1986, Meyers's group [252] synthesized the chiral NAD(P)H

Scheme 78 BMAR of benzoylformates by NAD(P)H model containing chiral groups at the C-3 position.

Scheme 79 BMAR of ethyl benzoylformate by NAD(P)H model 292 containing chiral groups at the N-1 position.

model **296a** without amide group at the C-3 position, and the reduction of methyl benzoylformate could afford 95% ee. When the C-5-substituent was the amide group (**296b**), the amide group competed favorably with the hydroxy group, resulting in a reversal of stereochemistry (Scheme 80).

Besides introducing chiral groups at the N-1, C-3 or C-4 positions, NAD(P)H models with other chiral modifications were also developed. Bourguignon and Levacher et al. [253,254] reported the synthesis of NAD(P)H models 297 with cyclic amide group successively. In the reduction of methyl benzoylformate, it was found that the out-of-plane C=O amide orientation may have important implications in the stereospecific hydrogen transfer. In order to avoid the side reaction of the enamine in the NAD(P)H models, Levacher's group [255] subsequently designed new axially chiral NAD(P)H model 298. On the one hand, the introduction of a benzene improved the stability of the NAD(P) H model, and on the other hand, the axial chirality and central chirality of the seven-membered cyclic lactam realized the good control of enantioselectivity. The synthesis of difunctional NAD(P)H model 299 in the pyrrolo[2,3-b]pyridine series was described by Levacher et al. [256]. The methyl mandelate was obtained in good enantioselectivity with either (S) or (R) configuration simply by changing the Mg^{2+} cation concentration. Kanomata's group [257] reported the chiral bridged NAD(P)H model 300 by cyclizing the C-2 and C-5 positions of the 1,4-dihydropyridine. The presence of bridge increased the steric hindrance of NAD(P)H models, and 99% ee could be obtained in the reduction of methyl

Scheme 80 BMAR of benzoylformates by NAD(P)H model containing chiral groups at the C-4 position.

benzoylformate (Scheme 81).

(2) C_2 -symmetrical chiral NAD(P)H models

Starting from optically pure *L*-amino acid esters, Kellogg's group [258] synthesized a series of C_2 -symmetrical NAD(P) H models **301** with various bridges. These NAD(P)H models have achieved the BMAR of ethyl benzoylformate with up to 90% ee. The enantiomeric excesses decreased with the increasing of the bridge length, which possibly affected the coordination between the bridged 1,4-dihydropyridine, Mg²⁺ cation, and carbonyl component (Scheme 82).

5.2 BMAR catalyzed by achiral NAD(P)H models

The BMAR participated by stoichiometric NAD(P)H models has achieved good results, but the harsh regeneration conditions of NAD(P)H models resulted in the poor atom economy, which limited the development of the BMAR. Through the simulation of the cyclic regeneration of coenzymes in biological processes, the scientists developed a series of renewable chiral NAD(P)H models, realizing the asymmetric reduction of carbonyl compounds, imines and so on, as shown in Scheme 83.

In 2002, Fish's group [259] successfully reduced the NAD(P)H model **302** into its corresponding 1,4-dihydroanalogue using rhodium as the catalyst precursor, and sodium formate as the hydride source. Subsequently, the highly enantioselective BMAR of ketone was realized with horse liver alcohol dehydrogenase. The first class of thiourea- and nicotinamide-based bifunctional organocatalyst **303** has been developed in 2007 by Connon's group [260]. In the BMAR of 1,2-diketone, the thiourea could activate the substrate by forming an intermolecular hydrogen bond avoiding the addition of stoichiometric Lewis acid, and the nicotinamide, as the NAD (P)H model, could regenerate in the presence of sodium dithionite. Unfortunately, the stereoselectivity of the reaction was poor albeit high activity (Scheme 84).

The regeneration of Hantzsch ester *in-situ* has been achieved by Ru complexes under hydrogen gas through the efforts of Zhou and coworkers [261]. In the presence of chiral phosphoric acid, the BMAR of benzoxazinones was realized with up to 99% ee. Although the use of hydrogen gas

Scheme 81 BMAR of methyl benzoylformate by NAD(P)H models with other chiral modifications.

Scheme 83 BMAR catalyzed by achiral NAD(P)H models.

as a reductant made this hydrogenation to be an ideal atom economic process, the harsh regeneration conditions of HEH and the presence of background reactions limited the scope of substrate. Therefore, it was necessary to explore NAD(P)H models which were easily regenerated *in-situ* under mild conditions (Scheme 85).

Most of the currently successful NAD(P)H models, such as HEH and 1-benzyl-1,4-dihydronicotinamide (BNAH), usually contained a dihydropyridine skeleton which played an important role in the hydride transfer process. Based on the dihydropyridine skeleton, a new and easily regenerable NAD(P)H model 9,10-dihydrophenanthridine (DHPD) was reported by Zhou and coworkers [262]. At room temperature, the DHPD could regenerate from phenanthridine by Ru complexes under hydrogen gas. Compared with 1,4-hydride transfer of the current NAD(P)H models, the 1,2-hydride transfer pathway occurring in DHPD-mediated reduction was better for controlling the enantioselectivity owing to the decrease in steric distance between substrate and catalyst. Besides benzoxazinones, the benzoxazines, quinoxalines, quinolines and alkynyl ketimines could also be hydrogenated with excellent activities and enantioselectivities using a

Scheme 84 BMAR of C=O by regenerable NAD(P)H models 302 and 303.

Scheme 85 BMAR of benzoxazinones by catalytic HEH.

catalytic amount of chiral phosphoric acid (Scheme 86).

Encouraged by the successful application of DHPD, 4,5dihydropyrrolo[1,2-a]quinoxalines (DHPQ), a series of tunable and regenerable NAD(P)H models, have been synthesized easily through the mild partial hydrogenation of corresponding pyrrolo[1,2-a]quinoxalines (PQ) by Zhou's group [263]. Subsequently, the biomimetic asymmetric hydrogenation of benzoxazines proceeded well with excellent yields and enantioselectivities when the chiral phosphoric acid was used as the transfer catalyst (Scheme 87).

Besides transition metal ruthenium complexes, inexpensive metal complexes could also enable *in-situ* regeneration of NAD(P)H models. In 2003, Beller and coworkers [264] demonstrated that iron catalysts were not only responsible for the regeneration of NAD(P)H model phenanthridine, but also acted as the Lewis acid to promote the transfer hydrogenation of methyl benzoylformate. The desired product could be obtained in excellent yield and moderate enantioselectivity. When Lewis acid was replaced by chiral phosphoric acid, the BMAR of benzoxazinones has been accomplished in high yields and enantioselectivities (up to 96% yield, 96% ee) [265] (Scheme 88).

5.3 BMAR catalyzed by chiral NAD(P)H models

Through the simulation of the coenzyme circulation process *in vivo*, the *in-situ* regeneration of coenzyme NAD(P)H models was successfully achieved. With the continuous deepening of people's research, various achiral regenerable NAD(P)H models have been designed and synthesized, and widely used in the reduction of diverse substrates. However,

Scheme 86 BMAR of C=N by catalytic phenanthridine (color online).

Scheme 87 BMAR of benzoxazines by catalytic pyrrolo[1,2-a]quinoxaline.

Scheme 88 The regeneration of phenanthridine by iron catalysts.

with the change of substrates, chiral transfer catalysts must be re-screened. Thus, the further application of this method is limited by the kind of chiral transfer catalysts. To solve the above challenges, in the new generation of BMAR system, the chiral environment of the transfer catalyst is transferred to the NAD(P)H model. Therefore, only commercially available achiral transfer catalysts need to be screened, and the substrate range of BMAR should be further expanded (Scheme 89).

In 2019, Zhou's group [266] introduced the chirality of the ferrocene skeleton into the NAD(P)H model, and synthesized the new chiral regenerable NAD(P)H model FENAM, which was easy to regenerate under hydrogen gas using a ruthenium catalyst. The BMAR of nitrogen-containing aromatic heterocyclic compounds and tetra-substituted electrondeficient olefins could be achieved in excellent yields and diastereo- and enantioselectivities by using hydrogen as the terminal reducing agent, ruthenium complex as the regeneration catalyst, and simple Lewis acid (Sm(OTf)₃ or Yb(OTf)₃) as the transfer catalyst (Scheme 90).

Subsequently, Zhou's group [267,268] changed the transfer catalyst from Lewis acid to simple Brønsted acid, which achieved the asymmetric reduction of imines and nitrogencontaining heteroaromatics with excellent results. A series of chiral amines could be synthesized (Scheme 91).

Besides Lewis acid and Brønsted acid, the organic catalyst

Scheme 89 BMAR catalyzed by chiral regenerable NAD(P)H models (color online).

urea could be also used as the transfer catalyst. In 2020, Zhou's group [269] found that the organic catalyst urea could activate the substrate through hydrogen bonding interaction, and the BMAR of benzoxazinones and quinoxalineones was achieved with up to 98% ee (Scheme 92).

Considering that the ferrocene skeleton is unstable under strong acid or oxidation conditions, Zhou's group [270] introduced a more rigid and stable [2.2]paracyclophane skeleton into the NAD(P)H model, and synthesized the new chiral regenerable NAD(P)H model CYNAM. The catalytic efficiency and stability have been improved to a certain extent compared with FENAM. Using ruthenium as the regeneration catalyst and simple Brønsted acid as the transfer catalyst, the BMAR of imines and nitrogen-containing heteroaromatics was realized with high activities and enantioselectivities (Scheme 93).

Similarly, using ruthenium as a regeneration catalyst and simple Brønsted acid or Lewis acid as the transfer catalyst, the BMAR of electron-deficient tetra-substituted olefins could be successfully completed. The *in-situ* alkylation with allyl group delivered highly enantioenriched stable products with two continuous stereocenters and one quaternary carbon center (up to 99% yield, 99% ee, >20:1 dr). Pleasingly, the chiral bioactive podophyllotoxin analogue could be concisely synthesized for the first time using the hydrogenated product as the key intermediate. Furthermore, Zhou's group [271–273] also found that the BMAR of 3-sulfonylcoumarin substrates could be directly realized, without transfer catalyst by regulating the reaction temperature. A broad range of highly diastereo- and enantiomerically enriched 3-sulfonyl dihydrocoumarins could be conveniently prepared with up to 99% yield, >20:1 dr and 99% ee (Scheme 94).

5.4 Summary and perspectives of NAD(P)H-based biomimetic asymmetric catalysis

The biomimetic asymmetric reduction (BMAR) catalyzed by NAD(P)H has made some progress, from the early stoichiometric simulation to the current regenerable simulation, which showed excellent hydrogen transfer ability and high stereoselectivity in asymmetric reduction of carbon-carbon

Scheme 90 BMAR catalyzed by FENAM and Lewis acid.

Scheme 91 BMAR of C=N catalyzed by FENAM and Brønsted acid (color online).

Scheme 92 BMAR of C=N catalyzed by FENAM and organic catalyst urea.

Scheme 94 BMAR of tetra-substituted olefins catalyzed by CYNAM.

double bond, carbon-nitrogen double bond and carbonoxygen double bond. However, the research field is still in the early stage of development. At this stage, a prominent problem is that the efficiency of this biomimetic catalytic system is not high, and the amount of biomimetic catalyst usually needs to be 10 mol%–20 mol%. Thus, the more efficient NAD(P)H chiral biomimetic catalytic systems need to be developed. In addition, owing to the couple of NAD(P)H and NAD(P)⁺, the stereoselective dehydrogenative oxidation based on coenzyme NAD(P)H should be explored in the future. With the further development of this field, BMAR based on coenzyme NAD(P)H will become a new method for synthesis of the chiral molecules.

6 Flavin-based biomimetic asymmetric oxidation

The discovery of simple and efficient catalyst systems for asymmetric oxidations of organic substrates is a challenging task of catalytic chemistry [274]. Simulation of the functions of enzymes such as flavoenzymes cytochrome P-450 using simple organocatalysts and transition metal catalysts have led to the discovery of biomimetic catalytic oxidation reactions [275–277]. In particular, flavin-catalyzed oxidation is one of the attractive approaches for designing environmentally benign catalytic oxidation reactions with organocatalysts [23,275]. There are three important flavins with unique functions in nature, which are riboflavin, flavin mononucleotide (FMN), and flavin adenine dinucleotide (FAD) [278-284]. Flavin-containing enzymes have three major functions: monooxygenase family, as a member of oxidase family, and as a member of the electron-transferase family (Figure 15). In this regard, flavin-dependent monooxygenases are biological agents responsible for the oxidation of substrates by activation of molecular oxygen to transfer oxygen atoms to the substrates [285], while oxidases are dehydrogenating agents. Given emerging focus on biomimetic catalysis, this review summarizes advances of biomimetic flavin catalysts in asymmetric oxidation [278].

The catalytic cycle of the FAD-containing monooxygenase (FADMO) has been well elucidated using its simple analogue 5-ethyl-3-methyllumiflavin as shown in Scheme 95. FIEtH (A) reacts with molecule oxygen to generate hydroperoxyl species FlEtOOH (**B**) [286]. Subsequent oxygen transfer from **B** to substrate S provides oxidized product SO with the concurrent formation of hydroxyl species FlEtOH C [287]. Acid promoted dehydroxylation of C gives the oxidized flavin $FlEt^+$ (**D**). Reduction of **D** by hydrogen donor NAD(P)H could regenerate FlEtH (A) for the next catalytic cycle. Alternatively, the highly electrophilic FIEt+ (**D**) could be also attacked by H_2O_2 from active species FlEtOOH (**B**) which was isolated for the first time by Bruice and coworkers [288] in 1976. It should be noted that oxidation ability of FlEtOOH is very powerful and 104 times stronger than H_2O_2 [289]. Interestingly, FlEtOH could be readily transformed

Figure 15 Flavin-cofactors (color online).

Scheme 95 Catalytic cycle for simple analogue 5-ethyl-3-methyllumiflavin.

into FlEtOOH upon treatment with H_2O_2 . Thus, the oxidation of a substrate with H_2O_2 in the presence of catalytic amount of FlEtOH should also occur. From the viewpoint of practicality, the catalytic cycle **D-B-C-D** is more practical by avoiding the involvement of NAD(P)H. On the other hand, the robustness of FlEt⁺ (**D**) makes flavinium salts benchstable organocatalysts.

It has been reported that the interaction of a substrate with a particular flavoprotein involved the interaction with the *Si*and *Re*-face of the flavin. The reason is to fix the chiral reaction site by hydrogen bonding and π - π stacking interaction. Thus, asymmetric catalytic oxidations could be performed using a proper chiral flavin organocatalyst. In this aspect, two important classes of asymmetric oxidations, sulfoxidations and Baeyer-Villiger oxidations, were systematically studied. A variety of flavin-based chiral organocatalysts were synthesized and the representative examples are listed in Figure 16.

6.1 Asymmetric oxidation of thioethers

Chiral sulfoxides are of great importance in both synthetic and medicinal chemistry. In this vein, Esomeprasol [(S)omeprazil, NEXIUM®] [290], psychostimulant armodafinil [(R)-modafinil, NUVGILTM] [291], (R)-lanoprazole, and (R)-sulindac are examples of enantiomerically pure sulfoxides used as pharmaceutical substrates. Although numerous asymmetric methods have been developed for construction of these flameworks [292], the use of flavinbased organocatalysts is able to provide environmentally benign and attractive alternatives.

The enantioselective sulfoxidation could be traced back to 1988 when Shinakai and coworkers [293] reported a planar chirality featured N(5)-ethylated flavinophane (+)-304 as an asymmetric autorecycling catalyst for mono-oxygenation of methyl aryl sulfides in the presence of an excessive amount of 35% aqueous H_2O_2 (Scheme 96). The corresponding chiral sulfoxides were obtained with up to 65% ee value in CH₃OH/H₂O. They found that both the chemical and optical yield increased with increasing water concentration in the solvent. These asymmetric sulfoxidations are highly useful examples catalyzed by a non-acid and non-base organocatalyst albeit with only moderate enantioselectivities. A plausible reaction mechanism was proposed as elucidated in Scheme 96. Electrophilic flavinophane (+)-304 is attached by H_2O_2 to form the hydroperoxy species **304-OOH**. Delivery of oxygen from **304-OOH** to sulfide furnishes sulfoxide with the concurrent formation of hydroxy species 304-OH. Dehydroxylation of 304-OH regenerates (+)-304 for the next catalytic cycle.

Cibulka and coworkers [294] developed a novel planar chiral flavinium salt (–)-305, which bears a phenyl cap that covers one side of the isoalloxainium skeleton plane (Scheme 97). The racemic form of 305 showed high turnover number with 870 for oxidation of thioanisole using 30% aqueous H₂O₂. Up to 54% enantioselectivity was observed when the reaction was carried out with enantiomer of (–)-305. The covalently bonded phenyl "cap" in (–)-305 covers one side of the isoalloxainium skeleton, allowing the access of H₂O₂ and the substrate only from the uncovered face of the flavin moiety [295]. Comparison of the enantioselectivity of the oxidation of thioanisole and cyclohexyl methyl sulfide showed that π - π stacking between 305-OOH and substrate is crucial to achieve high chiral induction.

In 2012, Yashima and coworkers [296] introduced a mainchain optically active riboflavin polymer for asymmetric catalysis. Polymer **306** was prepared from naturally occurring riboflavin (vitamin B_2) with supermolecularly twisted helical structure. Asymmetric sulfoxidation of sulfides using H_2O_2 yielded sulfoxides with up to 60% ee, whose enantioselectivity is higher than that delivered by the mono-

Figure 16 Representative chiral flavin-based organocatalysts for asymmetric oxidations (color online).

Scheme 96 Flavinophane 304-catalyzed enantioselective sulfoxidations.

meric catalyst (30% ee). This result revealed that the supermolecular chirality induced in the riobofalvincontaining polymers seemed to play a significant role in the enantio-determining step. To further understand the origin of the enantioselectivity, they proposed a transition state model

Scheme 97 Flavin (-)-305-catalyzed enantioselective sulfoxidations (color online).

as shown in Scheme 98. They assumed that polymer **306** may predominantly form a *Re-Re* stacked duplex, to which the nucleophilic addition of H_2O_2 occurs from the opposite site of *Si* face, generating the hydroperoxy adduct. The sulfide approaches the hydroperoxy species in such a way that the phenyl ring of the substrate preferentially interacts with the aromatic group of the poly *via* hydrophobic π -stacking to provide (*S*)-sulfoxide.

The stereodiscrimination in above sulfoxidations is predominantly controlled by weak π - π interaction between the flavin hydroperoxide and the aromatic ring of sulfide. It could be expected that catalytic performance could be further improved by an approach inspired by enzyme-like catalysis which takes advantage of a chiral substrate-binding site to control the stereoselectivity. To this end, Cibulka, Kraus, and coworkers [297] designed flavin-cyclodetrin conjugates as enzyme mimics capable of significant improvement of reaction rate in neat aqueous media as well as providing a chiral environment by cyclodextrin cavities. They found that N(1)- β -cyclodextrin-flavin conjugate **307a** with a linkage of an amide bond could oxidize aryl methyl sulfide in aqueousmedia in high efficiency (0.2 mol% catalyst loading) using hydrogen peroxide as the oxidant. This reaction tolerated a broad spectrum of substrate scope and corresponding sulfoxides were obtained with up to 80% ee value (Scheme 99). As a comparison, the use of a mixture of β cyclodextrin and 5-ethyl-1,3-dimethylalloxazinium salt in lieu of conjugate 307a under otherwise identical reaction conditions showed lower efficiency and provided no de-

Scheme 98 Polymer 306-catalyzed enantioselective sulfoxidations (color online).

tectable enantioselectivities, indicating that covalent linking of flavin and β -cyclodextrin components is essential [297]. The use of amide-linked N(1)- β -cyclodextrin-flavin conjugate 307b and N(3)- β -cyclodextrin-flavin conjugate 308 in oxidation of p-tolyl methyl sulfide provided sulfoxide with inferior enantioselectivity (Scheme 99) [298,299]. Interestingly, N(1)- β -cyclodextrin-flavin conjugates **307a** and **307b** showed excellent chiral induction (80%-91% ee) in sulfoxidation of hindered dialkyl sulfides such as cyclohexyl methyl sulfide and tert-butyl methyl sulfide (Scheme 99) [298]. In particular, 91% ee was achieved for the oxidation of tertbutyl methyl sulfide, which represented the highest value at that time for this substrate using synthetic (non-enzymatic) catalysts. Recently, they developed cyclodextrin-flavin conjugates by click chemistry to further extend scope of flavin-based organocatalysts as represented by N(1)- β cyclodextrin-flavin conjugate 309 [300]. Unfortunately, only low ee values were observed for sulfoxidations of various of sulfides (Scheme 99).

6.2 Asymmetric Baeyer-Villiger oxidation

Asymmetric Baeyer-Villiger (B-V) oxidation of prochiral cyclic ketones is one of the most straightforward manners to access optically active lactones. Due to the moisture- and air-sensitivity, transition metal catalysis in this field encounters

Scheme 99 Flavin-cyclodextrin conjugates-catalyzed enantioselective sulfoxidations (color online).

problematic issues including incompatibility of aqueous H_2O_2 or requirement of stoichiometric additives. Therefore, the development of highly efficient methods with environmentally benign oxidants is a goal in this area [301,302].

Murahashi, Imada and coworkers [303] elegantly developed a novel planar-chiral bisflavinium percholorate 310 with a backbone of (S,S)-1,2-diaminocyclohexane. With aqueous H₂O₂ as the oxidant, **310** could efficiently catalyze B-V rearrangement of 3-arylcyclobutanones in an enantioselective manner. The corresponding γ -lactones were obtained with 61%-74% ee values (Scheme 100). This method requires low temperature and long reaction time (6 days), which has lower efficiency in terms of both reactivity and enantioselectivity than chiral phosphoric acid catalyzed systems [304,305]. They proposed a plausible catalytic cycle as shown in Scheme 100. The enantioselectivity is induced by face selectivity in the formation of Criegee adduct. Since one face of the catalyst is completely blocked, the substrate would be attached by the opposite site of the other flavin group. The asymmetric induction is likely induced by hydrophobic π - π stacking between the phenyl ring of the substrate and that of the catalyst to fix the direction of the substrate. Nucleophilic attack of the hydroperoxylflavin at the carbonyl carbon of the substrate takes place from the opposite side of the phenyl group of the substrate. Thus, a subsequent 1,2-rearrangement occurs antiperiplanar to the

Scheme 100 Bisflavinium **310**-catalyzed enantioselective B-V reaction of 3-substituted cyclobutanones (color online).

leaving group to give the desired (S)- γ -lactone.

The difficulty in attaining chiral induction using flavinbased organocatalysts stems from their conformational changes [306–308]. They cycle between a "bent (hydroperoxide)" form and a "planar (flavinium)" form during the redox cycle. The catalyst designed by Murahashi and coworkers [307] is to block one face of the flavin with a covalently bound chiral cap. The substrate therefore approaches and reacts on the opposite site of the chiral cap, leading to low efficiency of chirality transfer. To this end, Yamamoto and coworkers [309] developed a self-assembled ion-pair organocatalysis for asymmetric B-V oxidation of 3-substituted cyclobutanones using 30% aqueous H_2O_2 as the oxidant. The combination of (R,R)-1,2-diphenylethylenediamine-based flavinium chloride 311 with dihydroguinine dimer (DHQ)₂PHAL is responsible for enhancing catalytic efficiency and stereoselectivity.

The protocol is applicable to structurally diverse 3-substituted cyclobutanones, delivering good to excellent enantioselectivities. To explain the importance of ion-pair formation in chiral induction, they proposed a plausible mode of the transition state for enantio-determining step, as illustrated in Scheme 101. Flavinium binds to either side of the $(DHQ)_2PHAL$ with a selective orientation set by π - π stacking and ionic interaction. Subsequently, H_2O_2 attacks iminium moiety of **311** to form hydroperoxyl species. The hydroperoxyl group then attacks the less hindered side of the carbonyl carbon of 3-phenylcyclobutanone to form a Creigee intermediate that undergoes H-bonding facilitated 1,2-rearrangement.

6.3 Asymmetric oxidative esterification, thioesterification, and amidation

The cooperative catalysis involving flavin could provide new platforms for asymmetric oxidation. Oxidative chiral Nheterocyclic carbene (NHC) catalysis open a new avenue in NHC chemistry [310]. However, the requirement of hazardous oxidants as well as stoichiometric waste is the main hurdle. To this end, Yashima, Iida, and coworkers [311] employed redox-active riboflavin by uptake of molecule oxygen as the terminal green oxidant, realizing cooperative oxidative NHC-catalyzed esterification, via kinetic resolution, giving unreacted alcohols with moderate to excellent ee values (Scheme 102). In addition, the present method could also be applied to the oxidative thioesterification of thiols and amidation of amines, although the selectivity for the enantioselective processes (as well as the efficiency) is still modest or low at this stage. A proposed mechanism is elucidated in Scheme 102. Reaction of thiazolium-based chiral NHC 312 with aldehyde forms Breslow intermediate E. Immediate oxidation of E by flavin catalyst 313 provides chiral acylation reagent F along with the formation of reduced flavin 313_{red} which could regenerate 313 through the

Scheme 101 Flavin 311/(DHQ)₂PHAL-catalyzed enantioselective B-V reaction of 3-substituted cyclobutanones (color online).

Scheme 102 Oxidative esterification, thioesterification, and amidation enabled by chiral NHC 312/riboflavin 313 synergistic catalysis (color online).

electron transfer process from molecular oxygen for the next redox cycle. Nucleophilic replacement of thiazolium in \mathbf{F} by secondary alcohols, thioalcohols, and amines provides optically active esters, thioesters, and amides and unreacted nucleophiles.

6.4 Summary and perspectives of flavin-based biomimetic asymmetric oxidation

Flavin-based biomimetic organocatalysts have been successfully used in asymmetric sulfide oxidation, Baeyer-Villager oxidation, and oxidative esterification/thioesterification/amidation using environmentally benign oxidants hydrogen peroxide and molecule oxygen under mild conditions. However, the reaction types and substrate scopes are still very narrow, and chiral induction is in a moderate level. Thus, this field is still on the horizon, which is mainly due to the lack of flavins with competent privileged scaffolds that could provide proper chiral pockets and suitable secondary interaction with substrates. The development of novel chiral flavin catalysts will certainly open a new avenue in this area. We also believe that flavin-involved synergistic catalysis will lead to the development of further unique and more efficient tandem reactions promoted by multi-catalyst systems as observed in the cell [312,313].

7 Hydrogenase-based biomimetic asymmetric catalysis

Hydrogenases are highly efficient redox enzymes for H_2 . On the one hand, hydrogenases can efficiently catalyze the reduction of protons to hydrogen to achieve a pollution-free hydrogen evolution. On the other hand, they can also catalyze the reversible cleavage of hydrogen and promote the reduction of a variety of unsaturated bonds [314].

Hydrogenases consist of two parts: the protein shell as reaction pocket and the coenzyme as the active site. Accordng to the central metals of the active sites, hydrogenases can be classified into three categories: [Fe]-hydrogenases, [FeFe]-hydrogenases, and [NiFe]-hydrogenases. The active centers of the latter two types of enzymes are binuclear organometallic complexes [315]. The protein structures of all these three types of enzymes contain gas channels that facilitate the diffusion of hydrogen into the active sites. In addition, the structures of hydrogenases generally contain ionized amino acid residues that promote proton transfer and iron-sulfur clusters that promote single electron transfer. Both of them play key roles in the heterolytic cleavage of hydrogen.

Biomimetic chemistry of hydrogenases has been a frontier topic. The researchers expect to utilize hydrogen under mild conditions like nature. Meanwhile, since hydrogen is a very clean energy source, the researchers also try to develop efficient biomimetic hydrogen evolution catalysts under electrocatalytic or photocatalytic conditions by mimicking hydrogenase, so as to alleviate the increasingly tight energy problem [316].

Some progress has been made in field of biomimetic cat-

alysis for all of the three hydrogenases, especially of [FeFe]hydrogenase (Figure 17). Researchers designed and synthesized a series of chiral catalysts by combining core structure of hydrogenases with asymmetric catalysis, and realized numerous efficient asymmetric hydrogenation reactions [317].

7.1 Biomimetic hydrogenation catalysts based on [FeFe]-hydrogenases

Among the three hydrogenases, [FeFe]-hydrogenases catalyze hydrogen evolution from protons with the highest catalytic efficiency [318]. The [FeFe]-hydrogenases isolated from Desulfovibrio desulfurican and Clostridium pasteurianum can catalyze the reduction of protons to hydrogen at rate of 9,000 and 6,000 mol s⁻¹, respectively [319,320]. Moreover, the [FeFe]-hydrogenase can also catalyze the oxidation of hydrogen reversely.

The active site of [FeFe]-hydrogenase is a [2Fe2S] subcluster [321], in which the two Fe centers are bridged by a bis(thiol) anion ligand and a carbonyl group. The linking group of two S atoms can be N–H group, which plays an important role in assisting the Fe center to activate H_2 . While the Fe center activating hydrogen gas through heterolysis cleavage, N–H group acts as an internal base to bind the

Figure 17 Structure of hydrogenases and representative biomimetic catalysts (color online).

proton. In addition, [FeFe]-hydrogenase has a [4Fe4S] cluster attached to the cysteine, which promotes the electron transfer during the hydrogen transfer (Scheme 103) [322].

Coincidentally, the mode of N-H ligand assisted hydrogen activation in [FeFe]-hydrogenase has long been demonstrated in a series of efficient and highly selective artificial hydrogenation catalysts. The metal centers of these artificial catalysts are generally coordinated to more than three heteroatoms (N, P, O, S, etc.), and these coordination sites contain more than one N-H group (Scheme 104a). At the beginning of the catalytic cycle, the proton on the N-H group and the anionic ligand (e.g., -Cl) on the metal center of the catalyst precursor are removed by base, and then the nitrogen obtains the proton after H₂ heterolytic cleavage, while forming the active M-H species. Mechanistic studies reveal that alcohols can assist this process to complete the activation of hydrogen through a six-membered ring transition state, which is more favorable than the direct activation of hydrogen through a four-membered ring transition state (Scheme 104b) [323].

The hydride on the metal and the proton on the nitrogen in the active catalyst can be matched electrically with a polar double bond and achieve the transfer of hydrogen from the catalyst to the substrate through a transition state of a sixmembered ring. Computational and experimental results indicate that alkali metal ions can also assist this process instead of protons (Scheme 104c) [324]. Besides, compared with the real hydrogenases, these artificial catalysts can be easily synthesized and modified due to their simpler structure. Therefore, it's feasible to introduce chiral structures into the ligands to achieve stereoselective control in the hydrogen transfer process so as to achieve asymmetric hydrogenation (Scheme 104d). In recent years, asymmetric hydrogenation and transfer hydrogenation based on this mode have been rapidly developed, and a large number of catalysts have been designed and synthesized to be successfully used for the asymmetric reduction of polar double bonds (typically, C=O and C=N).

As early as 1986 (Scheme 105), Shov et al. [325] disclosed that cyclopentadienone anion Ru complex 314 reversibly catalyzed the reduction of cyclohexanone in the presence of H₂. The mechanism of this hydrogenation reaction involves the critical process of synergitic hydride transfer from the metal and proton transfer from the oxygen to polar double bonds [326]. In 2007, Casey and Guan [327a] found that the cyclopentadienone anion coordinated iron complex 315, known as Knölker complex, could hydrogenate aromatic aldehydes, arvl alkyl ketones, arvlalkyl imines, and C=C of α,β -unsaturated ketone at a hydrogen pressure of 3 atm. Subsequently, Wills and Gennari [327b-e] made some chiral modifications for Knölker complex but failed to achieve good enantioselectivity in hydrogenation of ketones. In 2011, Beller et al. [328] used chiral phosphoric acid and Knölker complexes together to achieve highly enantioselective asymmetric hydrogenation of imines with up to 98% ee.

In 1995, Noyori's group [329] developed the chiral ruthenium-bisphosphine/diamine complex 316 [RuCl₂(BI-NAP)(diamine)]. In the asymmetric hydrogenation of acetophenone catalyzed by 316, turnover number (TON) could be more than one million. This catalyst and its ana-

Scheme 103 Mechanism for hydrogen activation catalyzed by [FeFe]-hydrogenase (color online)

Scheme 104 Mechanism of asymmetric hydrogenation for artificial catalysts (color online).

logues are also highly efficient catalysts for the hydrogenation of various ketones with up to 99% ee. In the same year, the group reported the chiral ruthenium-diamine complex **317** [Ru-TsDPEN], which effectively catalyzed the asymmetric transfer hydrogenation of aryl alkyl ketones with an enantioselectivity of up to 98% ee [330]. Wills *et al.* [331] and Ikariya *et al.* [332] modified the scaffold of this complex later by using linkers to connect the benzene ring with the chiral diamine to further increase the stability of the catalyst. The chiral ruthenium-diamine complex **318** developed by Ikariya achieved up to 30,000 TON and 99% ee in the asymmetric transfer hydrogenation of aryl alkyl ketones.

Zhang and coworkers [333] performed extensive and excellent work on asymmetric hydrogenation. In 1998, they developed the Ru-ambox complex **319** with a tridentate N ligand. This complex exhibited enantioselectivity (up to 98% ee) comparable to Noyori's Ru-TsDPEN catalyst in transfer hydrogenation, and catalyst **319** was more active when the reaction was carried out at higher temperature, while the enantioselectivity was maintained [333e].

In 2008, Baratta and coworkers [334] developed a chiral Os complex **320** modified by a non-chiral CNN tridentate ligand and a chiral bisphosphine ligand (Josiphos) to achieve asymmetric transfer hydrogenation of aryl alkyl ketones. The chiral Os catalyst exhibited very high activity with turnover frequency (TOF) up to 111 s^{-1} and with 97% ee as well. Direct asymmetric hydrogenation of aryl alkyl ketones also was achieved in methanol solvent and at 5 atm hydrogen pressure.

Zhou's group [335] did remarkable work in the field of asymmetric hydrogenation. Their chiral spiro PNN-type ligand modified Ir complex **321** developed in 2011 is a superhighly efficient catalyst for asymmetric hydrogenation. In the asymmetric hydrogenation of simple ketones, up to 99.9% ee and up to 4,550,000 TON (the enantioselectivity still remains 98% ee at this point) were achieved. It is indicated that this chiral catalyst is extremely stable and does not undergo decomposition during the entire reaction process [335a]. This spiro catalyst is the most efficient chiral molecular catalyst to date. In 2020, they developed a spiro PNP-type ligand modified Ir complex **322** with more crowded chiral pocket, which achieved the most challenging asymmetric hydrogenation of bis-alkyl ketones and gave more than 90% ee in most cases [335c].

Morris and coworkers [336] made in-depth studies in the field of iron-catalyzed asymmetric hydrogenation and transfer hydrogenation. In 2013, they developed a tetradentate bisphosphine/bisamine-iron complex **323**, which exhibited very high activity (TOF up to 200 s^{-1}) in transfer hydrogenation reactions of ketones and imines, and high enantioselectivity in the hydrogenation of aryl alkyl ketones and arylalkyl imines [336c].

In 2014, Gao and coworkers [337] developed a ligand **324a** with structure of 22-membered ring. Using this macrocycle ligand and Fe₃CO₁₂ together could catalyze the asymmetric hydrogenation of aryl alkyl ketones. At a catalyst-loading of 0.5 mol%, more than 90% ee were achieved for most substrates. This catalyst could also hydrogenate the carbonyl groups of β -ketoester with up to 99% ee. In 2015, Mezzetti's group [338] reported a bisphosphine/bisamine-iron complex **324b** with a structure of 14-membered ring. The stability of the metal center was enhanced by the introduction of two isonitrile ligands. The complex showed good enantioselectivity and substrate scope in the transfer hydrogenation of arylalkyl ketones. For various types of arylalkyl ketones, more than 90% ee were achieved.

In 2014, Morris and coworkers [336d] prepared a chiral PNP-Fe complex **325**. At 0.1 mol% catalyst-loading and low hydrogen pressure, the asymmetric hydrogenation of acetophenone catalyzed by **325** was accomplished with 80% ee. In 2017, Beller and coworkers [339] developed a chiral PNP-Mn complex **326**, which afforded up to 84% ee in the hydrogenation of arylalkyl ketones and bis-alkyl ketones. Notably, the analogous PNP-Ru complex can also be used in CO₂ reduction and fixation [340].

A number of tridentate ligands based on the ferrocene scaffold were successfully applied in the asymmetric hydrogenation reactions [341,333f–g]. Zhang's group [333f] designed a ferrocene based PNN tridentate ligand **327** containing a chiral oxazoline moiety, and used it in a highly efficient Ir-catalyzed hydrogenation with up to 1,000,000 TON and high enantioselectivities. Clarke and coworkers [341c] reported a PNN tridentate ligand modified manganese complex **328**, which was used as a catalyst in the asymmetric hydrogenation of aryl alkyl ketones with up to 97% ee.

Ding's group [342] also made very important contributions

Scheme 105 Development of biomimetic asymmetric hydrogenation catalyst based on [FeFe]-hydrogenase (color online).

in this field. This group developed a chiral PNN-Mn complex **329a** based on the pyridine backbone [342d]. In the asymmetric hydrogenation of ketones, **329a** exhibited good catalytic activity, up to 9,800 TON, and 85%–98% ee. Soon later, they also found that an analogous chiral manganese complex **329b** could also achieve dynamic kinetic resolution [343] of β -carbonyl amides by asymmetric hydrogenation with up to 99:1 dr and up to 99% ee [342e].

7.2 Biomimetic hydrogenation catalysts based on [Fe]hydrogenases

[Fe]-hydrogenase was first discovered in the hydrogenotrophic methanogenic archaea [344], which is not only a good catalyst for hydrogen production but also can catalyze hydrogen oxidation. In the presence of hydrogen, [Fe]hydrogenase can reversibly catalyze the reduction of methenyl-H₄ MPT⁺ to produce methene-H₄ MPT and proton, which is a key step in the microbial conversion of carbon dioxide to methane [345].

FeGP coenzyme is the active site of [Fe]-hydrogenase. The center of coenzyme has only one unsaturated fivecoordinated Fe atom and there is no iron-sulfur cluster but a special "2-pyridinol methylene acyl" ligand [346]. For [Fe]hydrogenase, besides the Fe's Lewis acidity can promote the heterolytic cleavage of the H-H bond, the sulfur atom on the cysteine or the hydroxyl on the pyridine ring can also play a proton-binding role in the process of hydrogen activation. DFT calculations revealed that during the cleavage of H_2 , the transition state TS1 that O ligand assists to bind proton is more favorable than the transition state TS1' that S ligand binds proton. Then more stable intermediate Fe-H^{δ^-}—H^{δ^+}-O is derived, followed by the transfer of hydride to MPT⁺ (Scheme 106) [347]. Notably, this hydrogenase also requires the assistance of O or S ligands for hydrogen activation (TS1 & TS1'), which is similar to [FeFe]-hydrogenase, but its hydride transfer and proton transfer are not concerted, which is significantly different from [FeFe]-hydrogenase.

Since the X-ray crystal structure of [Fe]-hydrogenase was determined by Shima *et al.* [346] in 2008, a number of active-site models of [Fe]-hydrogenase have been synthesized. These analogs synthesized early showed only structural similarity but did not display the ability of activating the hydrogen [348]. In 2016 (Scheme 107), Hu's group [349] replaced the two COs on the iron center with a bisphosphine ligand to obtain complex **330**. At the presence of hydrogen, complex **330** was able to reduce aryl aldehydes stoichiometrically. Then the complex would decompose into 2-methoxy-6-methylpyridine and iron salt coordinated by CO and bisphosphine.

In 2017, Rose and coworkers [350] reported a [Fe]hydrogenase based mimic **331a** containing anthracene scaffold. When I^{-} was exchanged by $[BAr_{F}]^{-}$, the complex can activate H₂ under mild conditions or grab hydrogen from the active C–H bond of imidazolidine to generate Fe-H species **331b**. Fe-H species can react with 2,6-di-*tert*-butyl-4-meth-oxyphenol to evolution hydrogen. A year later, the same group [351] developed a monoiron complex **332** by mod-ifying the mimetic complex **331a**. At the present of D₂, complex **332** can catalyze the reduction of imidazoline that is a simulation of reducing methenyl-H₄ MPT⁺ to methene-H₄ HMPT by [Fe]-hydrogenases.

In the field of [Fe]-hydrogenase-based biomimetic chemistry, another important breakthrough is the functional model complex 333 reported by Hu's group [352] in 2019. This complex, with manganese as the metal center, enables catalytic hydrogenation of C=C, C=N, and C=C. In addition, after reconstituting this manganese complex and apoenzyme, the "artificial hydrogenase" is also biologically active and can catalyze the reduction of methenyl-H₄ MPT⁺ under H₂ reversibly [353]. In 2020, they synthesized analogous acvlmanganese complex 334, whose ability of reducing polar double bonds was further enhanced. Combined with NAD(P)H analogue, this catalyst could also be used for the asymmetric reduction of C=N of benzoxazinones [354]. However, no example of [Fe]-hydrogenase-based mimics with H₂ to achieve asymmetric hydrogenation has been reported until now.

7.3 Biomimetic hydrogenation catalysts based on [NiFe]-hydrogenases

The active site of [NiFe]-hydrogenase is a Ni-Fe heterodinuclear structure with four cysteines coordinated to Ni through the S atom, two of which serve as the terminal groups and the others are also connected to Fe through the S atom. The Fe center is also surrounded by a CO and two CNs⁻. In the oxidized state of [NiFe]-hydrogenase (Ni-A or Ni-B), there is also a bridging oxygen ligand (generally H₂O, OH^{-} , or $O^{2^{-}}$) between Fe and Ni. After getting electrons and protons, the oxidative [NiFe]-hydrogenase will lose a H₂O and be reduced to Ni-SI state. Then the hydrogen goes through the heterolytic cleavage in the Ni center to get the Ni-R state. There is a H⁻ bridge attached to the Ni and Fe, while the proton is transferred to the sulfur atom of the cysteine. Ni-R state gives proton and electron to produce the Ni-C state, which further gives proton and electron back to the Ni-SI state [355]. Similar to the models of the other two hydrogenases, [NiFe]-hydrogenase also facilitates hydrogen cleavage by assisting the metal through the sulfhydryl group of cysteine. But it is different from the other two hydrogenases wherein the hydride is coordinated to both metals at the same time (Scheme 108).

There are relatively fewer studies on [NiFe]-hydrogenases mimics, and most of them developed have low hydrogen evolution efficiency, probably due to the complex structure

Scheme 106 Mechanism for hydrogen activation catalyzed by [Fe]-hydrogenase (color online).

Scheme 107 Development of biomimetic catalyst based on [Fe]-hydrogenases (color online).

of the heterodinuclear metallic center [356]. At present, [NiFe]-hydrogenases-based biomimetic chemistry has made progress mainly in the field of developing efficient artificial hydrogen evolution catalysts, but examples of catalytic hydrogenation using [NiFe]-hydrogenases mimics have not been achieved yet.

In 2007 (Scheme 109), Ogo's group [357] reported that the Ni-Ru dinuclear metal complex **335** can activate hydrogen in the aqueous phase to give Ru-H species. In 2013, the same group reported that the Ni-Fe complex **336** could activate

hydrogen under alkaline conditions to produce Fe-H species [358]. Under acidic conditions, Fe-H species can bind protons to produce hydrogen and regenerate **336**. Rauchfuss and coworkers synthesized [NiFe]-binuclear complexes **337a** [359] and borane-protected [NiFe] complexes **337b** [360], both of which could activate H₂ under mild conditions.

Based on the scaffold of bipyridine, Duboc *et al.* [361] synthesized [NiFe]-hydrogenase active-site models **338**, which could reduce protons to produce H_2 on a Hg-pool cathode. Foot-of-the-wave analysis disclosed a second-order

Scheme 108 Deactivation/reactivation mechanism for [NiFe]-hydrogenases (color online).

rate constant $k_{cat}=2.5\pm0.3\times10^4 \text{ M}^{-1} \text{ s}^{-1}$ and a TOF of 250 s⁻¹.

In recent years, the researchers developed numberous simple and stable photocatalysts for hydrogen evolution. Wu's group [362] made remarkable contribution in mimicking hydrogenases to achieve visible photocatalytic hydrogen evolution. They developed [NiFe]-hydrogenase-based mimetic catalyst of (dppe)Ni(μ -pdt)(μ -Cl)Ru(CO)₂Cl (**339**), which could catalyze hydrogen precipitation by proton reduction efficiently through both photocatalytic and electrocatalytic methods. The benchmark TOF of hydrogen production in the photocatalytic system is as high as 0.54 s⁻¹, and the mechanistic study in the electrocatalytic system shows that dimer of compound **339** is the real active catalytic species [362c].

7.4 Summary and perspectives of hydrogenase-based biomimetic asymmetric catalysis

Important progress has been made in biomimetic chemistry based on [FeFe], [Fe] and [NiFe] hydrogenases, demonstrating the great value and potential of hydrogenase-based biomimetic catalysts for applications in asymmetric hydrogenation, CO₂ reduction and fixation, and photolysis for hydrogen evolution. It should be noted that many artificial catalysts are not deliberately designed to mimic hydrogenases, but mechanistic studies have shown that they have similarities in the way of activating hydrogen and transferring hydrogen. Some of the highly efficient artificial hydrogenation catalysts have approached or even surpassed the enzyme catalysts in terms of activity. But the central metals of these super-highly active hydrogenation catalysts are generally based on 4d or 5d noble metals, such as Ru, Rh, Ir. Although there have been many successful examples of using abundant 3d metal catalysts in asymmetric hydrogenation reactions, the efficiency of most 3d metal catalysts is still much lower than that of noble metal catalysts.

On the contrary, hydrogenases show high catalytic activity with 3d central metals like Ni and Fe. The protein shell of the enzyme acts as a multi-dentate ligand around the catalytic center, not only stabilizing the structure of the active site, but also cunningly concealing it in the protein molecules, which effectively prevent the deactivation of the catalyst. It is difficult to directly replicate the effect of these complex protein structures in artificial catalysts by chemical synthesis. But based on the understanding of the enzymatic catalytic mechanism, we can expect to use more economical, sustainable and biocompatible 3d metals to achieve high catalytic activity and selectivity under mild reaction conditions. Therefore, understanding the reaction mechanism of enzyme

Scheme 109 Development of biomimetic catalysts based on [NiFe]-hydrogenase (color online).

catalysis, mimicking the key structure of enzymes, and performing biomimetic design of catalysts are the future directions to further improve the activity and selectivity of artificial catalysts.

8 Heme oxygenase-based biomimetic asymmetric catalysis

Heme oxygenase is an enzyme with iron porphyrin (or heme) as its auxiliary group (Figure 18). It is widely involved in the redox reactions in animals, plants, yeast, aerobic bacteria and anaerobic photosynthetic bacteria [363-365]. In 1958, Klingenberg [366] and Garfinkel [367] found that a pigment in the cell microsome had an absorption peak at 450 nm, named P450, after being reduced by carbon monoxide. In 1964, Omura and Sato [368,369] confirmed that P450 is indeed a protein. Heme oxygenase plays an important role in biological oxidation. In the currently known heme enzymes, there are more than 1,000 kinds of cytochrome P450 enzymes. Heme oxygenase has a strong catalytic function and can catalyze the directional oxidation of various foreign compounds, supporting reactions such as C-H bonds hydroxylation, double bond epoxidation, heteroatom oxidation, aromatic hydrocarbon oxidation and aldehyde and alcohol oxidation [25,370].

In the catalytic oxidation of alkanes by cytochrome P450 [371-373], the alkanes first bind to Fe(III) species (**A**) to obtain the ferric intermediate (**B**). This intermediate (**B**) is then reduced to Fe(II) ferrous species (**C**), which is then oxidized by oxygen to generate ferric-superoxo species (**D**). Subsequently, a second electron and a proton are transferred to the ferric-superoxo species (**D**) to produce a ferric(hydro) peroxo intermediate (**F**), which then combines with protons to release a molecule of H₂O to form a Fe(IV)=O species **G**,

Figure 18 Cytochrome P450 enzymes: structure and function (color online).

which is the real oxidative intermediate. Finally, alkanes are oxidized by this intermediate (**G**) by C–H bond cleavage and C–O bond formation. This last process may be cooperative or stepwise, involving hydrogen grabbing and oxygen rebound (Scheme 110).

Heme oxygenase is an oxidase with an iron porphyrin complex as its core, which is the key site in which catalytic functions are performed. Metalloporphyrin complexes can be used to simulate the catalytic function of heme oxygenase. Asymmetric catalytic simulations can also be achieved if chiral groups are introduced into porphyrin ligands. Similar to heme oxidase, metalloporphyrin complexes can form active catalytic species by activating molecular oxygen to undergo various reactions such as alkane C–H oxidation and alkene epoxidation.

This section mainly focuses on biomimetic asymmetric catalytic reactions based on heme oxygenase, and the most recent progress in the asymmetric epoxidation of olefins, asymmetric sulfoxylation of sulfides and asymmetric C–H bonds activation.

8.1 Metalloporphyrin-catalyzed asymmetric cyclization of alkenes

8.1.1 Asymmetric epoxidation of alkenes

The first example of asymmetric epoxidation of olefins

Scheme 110 Mechanism of hydroxylation of alkanes catalyzed by cytochrome P450 enzyme (color online).

catalyzed by metalloporphyrin complexes was published in 1983 when Groves *et al.* [374] used $\alpha\beta\alpha\beta$ -tetrakis(*o*-(*R*)hydratropamidophenyl)porphyrin (**340**) and $\alpha\beta\alpha\beta$ -tetrakis(*o*-[(*S*)-2'-carboxymethyl-1,1'-binaphthyl-2-carboxamido]phenyl)porphyrin (**341**) iron complexes in their exploration of the oxidation of various substituted styrene and aliphatic olefins-reactions with an ee value between 9% and 51%. Although the enantioselectivity of this reaction is only moderate, these findings promoted the development of a new field (Scheme 111).

Binaphthyl with axial chirality is a member of a class of privileged chiral ligands and have made outstanding contributions in the field of asymmetric catalysis. A series of chiral porphyrin metal complexes have been made by introducing binaphthyl structures into the porphyrin system (Figure 19).

In 1990, Grove *et al.* [375] synthesized vaulted metalloporphyrin (342). The roles of iron and manganese porphyrin complexes in the asymmetric epoxidation of olefins were studied and the enantiomeric excess of such reactions was found to be moderate (Figure 20, entry 1).

In 1991, Naruta *et al.* [376,377] designed and synthesized a novel C_2 -symmetric "Twin-Coronet" porphyrin of chiral binaphthyls, connected by ether bonds on both sides. In the epoxidation of aryl olefins catalyzed by iron porphyrin (343,

Scheme 111 Chiral iron-porphyrins for enantioselective epoxidation of olefins.

M=FeCl) and iodosobenzene, the ee of 2-nitrostyrene is as high as 89% (Figure 20, entry 2). In 1992, the same group investigated the effect of the central metal and oxidants on the epoxidation of olefins. The asymmetric epoxidation of *cis*- β -methylstyrene catalyzed by manganese complexes was found to have better ee values than that developed with iron catalysis [377].

In 1992, Collman *et al.* [378] connected two chiral binaphthyl groups with a macrocyclic ether structure, and introduced them into a porphyrin structure. The iron porphyrin

Figure 19 Porphyrin metal complexes containing chiral binaphthyl groups.

Figure 20 Asymmetric epoxidation of alkenes.

complex (**344**) obtained from "binap capped" porphyrin has the same behavior as other metalloporphyrin complexes in the epoxidation of terminal olefins (Figure 20, entry 3).

Collman *et al.* [379] prepared, C_2 -symmetric chiral porphyrin compounds (345) with binaphthyl handles in 1998. Using the iron porphyrin complexes (345), the corresponding epoxides can be obtained with excellent enantioselectivity under the oxidation of iodoylbenzene, $C_6H_5IO_2$ (Figure 20, entry 4). A naphthalene ring on metalloporphyrin could be oxidized to a quinone structure (347) during the reaction, and this may greatly improve the enantioselectivity of the reaction.

In 2000, Salvadori *et al.* [380] introduced a binaphthalene group to the *meso*-position of a porphyrin and obtained four atropisomers. Among these, the reaction of $\alpha\alpha\beta\beta$ -isomer iron complexes (348) was the best, and produced (*S*)-phenylethylene oxide in 47% yield and 57% ee (Figure 20, entry 5).

In 2000, Rose *et al.* [381] prepared a C_2 -symmetric chiral iron-porphyrin complex (349) containing binaphthalene and pentafluorophenyl, which was named "Seat" iron-porphyrin. The asymmetric epoxidation of styrene and pentafluorostyrene by the catalyst reached 59% and 85% ee, respectively (Figure 20, entry 6).

In 2004, Rose *et al.* [382] also developed a C_2 -symmetric bis(binaphthyl)porphyrin that differs structurally by only two CH₂ groups from their previously published structures. The metal complex (**346**) gave 75%–96% yields and 81%–97%

ee in the asymmetric epoxidation of olefins such as styrene (Figure 20, entry 7).

Chiral alcohols and amino acids are cheap and readily available chiral sources. In 1985, Mansuy *et al.* [383] introduced chiral phenylalanine into porphyrin compounds containing amino groups, and prepared "basket handle" iron porphyrin complexes (**350**) with L-phenylalanine, and "picket" iron porphyrins (**351** and **352**) (Figure 21). The "basket handle" iron porphyrin complexes could catalyze the epoxidation of *p*-chlorostyrene up to 50% ee, while "picket" iron porphyrins **351** and **352** delivered only 12% and 21% ee, respectively (Figure 22, entry 1).

In 1991, Momenteau *et al.* [384] introduced the acetylprotected chiral glucose group into tetraphenylporphyrin through a covalent bond, and synthesized the corresponding iron porphyrin and manganese porphyrin complexes (**353**). However, the enantioselective control exerted by these catalysts is less than ideal (Figure 22, entry 2).

In 1997, Gross *et al.* [385] synthesized iron porphyrin complexes (**354**, **355**) of a ketal-protected threitol derivative, and studied the complex catalyzed asymmetric epoxidation of alkenes under different conditions (Figure 22, entry 3).

In 2001, Smith *et al.* [386,387] introduced (R,R)-2,6-bis(1phenylbutoxy)phenyl and pentafluorophenyl into porphyrins and synthesized four iron porphyrins and a manganese porphyrin complex. The iron porphyrin complex (**356**) with four dialkoxyphenyl units is a poor catalyst for epoxidation. The activity, stability and selectivity of the catalyst were improved by introducing the smaller penta-fluorophenyl group in place of the 2,6-di(1-phenylbutoxy)phenyl group (Figure 22, entry 4).

In 2003, Boitrel [388] reported the synthesis of picketfence iron porphyrin complexes with L-prolinoyl as a chiral source. Four atropisomers were obtained, and the $\alpha\beta\alpha\beta$ atropisomer (**361**) had the best ee (34%) for the epoxidation of 1,2-dihydronaphthalene (Figure 22, entry 5). In addition, they also obtained bis-strapped iron porphyrin complexes by linking L-proline groups through amides, but unfortunately these bis-strapped iron porphyrin complexes did not work well in the asymmetric epoxidation of olefins [389].

In 2004, Higuchi *et al.* [390,391] described a novel method for the efficient synthesis of D_4 -symmetric chiral porphyrins using commercially available C_2 -symmetric diols as the chiral source. The epoxidation reaction of styrene catalyzed by **362** showed the moderate enantioselectivity. The ee value was significantly increased by introduction of electronwithdrawing groups on the styrene ring. They also examined the electronic effect of the styrene substituents on the porphyrin catalyst and found that the electron-deficient groups decreased the enantioselectivity and electron-donating groups increased the enantioselectivity.

In 1997, Halterman's group [392] prepared the D_4 -symmetric catalytic activity of their manganese complexes in the

Figure 21 Metalloporphyrin complexes containing chiral alcohols and amino acids.

epoxydation of aryl olefins (Figure 23). In the epoxidation of cis- β -methylstyrene, the methoxy-substituted manganese porphyrin metal complex (**369**) gave the best result (up to 83% ee).

In 2002, Yeung *et al.* [393] studied the effects of various organic bases on the asymmetric epoxidation of olefins catalyzed by Halterman's manganese porphyrin complexes (**368**). For the epoxidation of *cis*- β -methylstyrene, KHSO₅ was used as an oxidant. In the absence of an amine as an additive, the ee value was 43% and when DMAP was used as an additive, the ee value could be increased to 81%.

In 2006, Simonneaux *et al.* [394] used chiral metalloporphyrin (Fe, Ru) complexes functionalized with four vinyl groups to polymerize with styrene and divinylbenzene (or ethylene glycol) to obtain supported iron and ruthenium complexes (**370**). The heterogeneous asymmetric epoxidation styrene derivatives were carried out by using these polymers as catalysts, the ee was up to 75%.

In 2010, Bach et al. [395,396] introduced the concept of

hydrogen bond-directed reactions into the reactions catalyzed by ruthenium porphyrins (**372**). Rigid bulky sterically hindered chiral amide skeletons were introduced into porphyrin ligands with a Sonogashira reaction (Scheme 112a), and successfully achieved asymmetric epoxidation of alkenes with the ruthenium-porphyrin complexes. The catalytic epoxidation reaction uses 2,6-dichloropyridine-N-oxide as the oxidant, and the hydrogen bonding brings the substrate and the ruthenium-porphyrin complex into closer proximity, resulting in a highly enantioselective and regioselective reaction (Scheme 112b). The epoxidation reaction of 3-vinylquinolone reached up to 95% ee and 71% yield (Scheme 112c).

8.1.2 Asymmetric cyclopropanation of alkenes

Many drugs, natural products and important intermediates in organic synthesis contain a cyclopropane ring motif. The asymmetric cyclopropanation of alkenes with diazonium compounds and metalloporphyrin catalysis is significant. In 1999, the Gross's group [397] used porphyrin with a ketal-protected chiral diol, and examined the reaction of styrene and ethyl diazoacetate catalyzed by different metalloporphyrin complexes (Scheme 113a). When using the ruthenium porphyrin complex (**354**), they obtained an ee value of 58%.

In 2006, Che and coworkers [398] used Halterman's iron porphyrin chiral complexes (368) as catalysts to realize the insertion reaction of ethyl diazoacetate to styrene compounds. In this way, they synthesized a series of cyclopropane compounds with high diastereo- and enantioselectivity (Scheme 113b).

Simonneaux *et al.* [399] converted a Halterman porphyrin complex into a polymer, using the chiral porphyrin iron and ruthenium (**370**) as heterogeneous catalysts, and achieved the insertion of 2,2,2-trifluorodiazoethane to styrene, producing the optically active trifluoromethylphenylcyclopropane (Scheme 113c). In 2008, the same group used chiral Halterman porphyrin compounds (**368**) with sulfuric acid to obtain a water-soluble tetrasulfonated porphyrin complex

(371) [400]. Using this water-soluble chiral porphyrin iron or ruthenium in water for the asymmetric addition of ethyl diazoacetate to styrene, optically active *trans*-cyclopropyl ester compounds can be obtained (Scheme 113d). In 2009, Simonneaux et al. [401] also used chiral Halterman chiral iron porphyrin (368) (M=FeCl) as a homogeneous catalyst to asymmetrically add diazoacetophenone to styrene derivatives to obtain chiral cyclopropyl ketones (Scheme 113e). In 2014, Gallo *et al.* [402] synthesized a novel C_2 -symmetric binap-bis-strappedironporphyrin complex (373) (Scheme 113f). This complex (373) catalyzed the stereoselective cyclopropanation of α -methylstyrene with good reactivity, enantio- and diastereoselectivity (up to 99:1 dr), producing the trans structure with up to 87% ee.

In 2003, Zhang et al. [403] found that tetraphenylporphyrin cobalt could efficiently catalyze the cyclopropanation of arylalkenes with ethyl diazoacetate. Two chiral porphyrin cobalt complexes (374 and 375) were synthesized, and the asymmetrically catalytic reaction was rea-

Figure 25 Zhang's cobalt porphyrin metal complexes.

of base, and achieved the radical asymmetric cyclopropanation of olefins. When the cobalt porphyrin complex (**398**) is used, the corresponding cyclopropanation products can be obtained in high yield, and the diastereo- and enantioselectivity of the reaction can be effectively controlled (Scheme 115a). Zhang *et al.* [422] also realized the asymmetric radical cyclopropanation of dehydroaminocarboxylates, and obtained a series of amino acid derivatives with chiral cyclopropane skeletons (Scheme 115b). By fine-tuning the cavity environment, they also synthesized a series of new D_2 -chiral porphyrin complexes (**401–408**) [406]. The optimized Co porphyrin metal radical system can be widely applied to α pyridyl and other α -heterocyclic substituted diazomethanes, and can be used for asymmetric cyclopropanation of other olefins (Scheme 115c) [423]. They also realized the asymmetric cyclopropanation reaction between α -alkynyl diazomethane and olefins, catalyzed by a cobalt porphyrin metal complex (**391**) using the corresponding sulfonyl hydrazone generated *in situ* under basic conditions (Scheme 115d) [424].

Compared with intermolecular reactions, the intramolecular insertion reaction of diazo compounds to alkenes has been studied less. Zhang *et al.* [425,426] realized the intramolecular asymmetric cyclopropanation of alkenes, providing a powerful strategy for the stereoselective construction of complex [3.0.1] bicyclic systems (Scheme 116a). They also applied their cobalt-based metalloradical catalytic system to the stereoselective radical cascade reaction of 1,6-enynes with diazonium compounds. By using a cobalt porphyrin metal complex (**383**) as a catalyst, the radical cascade reaction of 1,6-enyne

Scheme 114 Cobalt-based metalloradicals catalyze asymmetric cyclopropanation of alkene.

with diazo compounds can be realized, and a series of cyclopropane-fused tetrahydrofuran compounds can be obtained with good yield and excellent stereoselectivity (Scheme 116b) [427].

8.1.3 Asymmetric aziridination of alkenes

Chiral aziridine derivatives play an important role in chemistry and biology and consequently, the enantioselective synthesis of aziridine and its derivatives is significant. The synthesis of aziridines by metal-catalyzed insertion of nitrenes into alkenes has received extensive attention due to the abundance and variety of alkenes. In 1997, Che *et al.* [428] used D_4 -symmetric Halterman manganese metalloporphyrin complexes (M=MnOH) (**368**) to catalyze the aziridination of

Scheme 115 Asymmetric cyclopropanation of sulfonyl hydrazone with alkenes.

styrene-type substrates, obtaining an enantiomeric excess of 43 - 68%. In 1999, Marchon *et al.* [429] used manganese and iron metalloporphyrin complexes (408) as catalysts to realize the asymmetric aziridine reaction of PhI=NTs with styrene (Figure 26). It is interesting that two different metals in this reaction have opposite stereoscopic configurations.

In 2008, Zhang's group [430,431] used the D_2 -symmetric chiral porphyrin cobalt complex (377) that they had developed to realize the asymmetric aziridination of aryl alkenes using diphenylphosphonoazide as a source of the nitrene (Figure 27a, entry 1). This reaction affords the desired *N*phosphine substituted aziridine compounds in moderate to high yields with good enantioselectivity. Other azide compounds including trichloroethoxysulfonyl azide (Figure 27a, entry 2) [432], fluorine substituted aryl azide (entry 3) [433], and trichloroethoxyformyl azide (entry 4) [434] can smoothly participate in the aziridination of alkenes, in the presence of a suitable cobalt porphyrin catalyst to give the corresponding product in high yield and with excellent stereoselectivity. In addition to the intermolecular aziridiation

Scheme 116 Intramolecular insertion reaction of diazo compounds to alkenes (color online).

Figure 26 Manganese and iron porphyrins catalyzed asymmetric aziridination of styrene.

(a) Asymmetric aziridination of alkenes

Figure 27 Cobalt-based metalloradicals catalyze asymmetric aziridination of alkenes.

of alkenes, Zhang's group [435] also realized the insertion reaction of intramolecular nitrenes into alkenes and efficiently constructed chiral [3.1.0]-bicyclic aziridines with high diastereo- and enantioselectivity (Figure 27b).

8.2 Metalloporphyrin-catalyzed asymmetric C–H bond activation

8.2.1 Asymmetric hydroxylation of C-H bonds

In 1989, Grove *et al.* [436] also used the synthesized vaulted metalloporphyrins (**342**) to catalyze the hydroxylation of C–H bonds. Using a chiral porphyrin iron complex

(M=FeCl) (**342**) as catalyst and iodoylbenzene (PhIO₂) as oxidant, a hydroxylation product of ethyl benzene was obtained in 40% yield and with 41% ee value. In 1990, they synthesized the corresponding manganese porphyrin catalyst (M=MnCl) (**345**) and compared it with the iron porphyrin catalyst (M=FeCl) (**345**) in the benzylic C–H bond hydroxylation reaction (Figure 28) [375].

In 1999, Gross *et al.* [437] introduced a ketal-protected chiral diol into the porphyrin skeleton, and synthesized a class of D_2 -symmetric chiral ruthenium porphyrin complexes (409). With ruthenium porphyrin (409) as the catalyst and 2,6-dichloropyridine nitrogen oxide as an oxidant, an asymmetric oxidation of a C–H bond on a tertiary carbon was achieved in 38% ee. The ruthenium porphyrin complex can also realize the kinetic resolution of secondary alcohols (Scheme 117).

Che *et al.* [438] reported the hydroxylation of C–H bonds in aromatic benzyl positions using 2,6-dichloropyridine nitrogen oxides as oxidants in the reaction catalyzed by ruthenium porphyrin catalysts with chiral norbornanes in the *meso*-position. In 2012, Simonneaux *et al.* [439] introduced four sulfonate groups into this chiral porphyrin compound and synthesized a water-soluble manganese porphyrin catalyst (**371**). The water-soluble manganese porphyrin catalyst can achieve asymmetric hydroxylation of alkanes in a water/ methanol system with ee values up to 57% (Figure 29).

In 2015, Bach and coworkers [440] introduced a rigid and large hindered chiral amide skeleton into porphyrin ligands, and the resulting porphyrin ruthenium complex successfully realized the C–H bond oxidative desymmetrization of an oxidized spiro-indole (Figure 30a). The hydroxyl intermediates obtained in this reaction are unstable and are further oxidized to ketones under the conditions of Swern oxidation or PCC oxidation to give chiral spiro-dicarbonyl compounds with ee up to 96%. In 2018 and 2020, Bach's group realized the asymmetric hydroxylation of 3-dimethyl-3-dimethyl-3-dihydroquinolone using a similar strategy (Figure 30b) [441] and 3-benzylidene quinolone (Figure 30c) [442] with a manganese porphyrin as the catalyst in the presence of io-dosobenzene, as oxidant, with a diastereoselectivity of up to 99%.

8.2.2 Asymmetric carbon-hydrogen bond alkylation

In 2012, Che's group [443] used Halterman's porphyrin iridium complex (413) to realize the asymmetric insertion reaction of diazonium compounds into 1,4-cyclohexadiene and tetrahydrofuran, which afforded the corresponding products with high yield and excellent enantioselectivity (Scheme 118a). Using the same catalytic system, they also realized the asymmetric intramolecular insertion reaction of diazo compounds into C–H bonds, obtaining the corresponding *cis*- β -lactone compounds (Scheme 118b) [444]. The reaction has high yield and excellent diastereoselec-

Reaction conditions: catalyst/iodosylbenzene/substrate = 1:100:1000, CH₂Cl₂ at 0 °C in the absence of oxygen.

Scheme 117 Hydroxylation of C–H bonds and kinetic resolution of alcohols.

tivity.

In 2014, Zhang et al. [445] used a Co-based metalloradical catalyst system for the asymmetric intramolecular C-H alkylation of acceptor or acceptor-substituted diazo reagents (Scheme 119a). Using the cobalt porphyrin metal catalyst, 1,5-C-H alkylation can be achieved to give 5-membered sulfolane derivatives with high yield and excellent enantioselectivity and diastereoselectivity. Through chiral ligand judicious modulation using bridged D_2 -symmetric chiral cobalt porphyrins as optimal supporting ligands, Zhang et al. [446] demonstrated the first Co-based metalloradical 1,4-C-H alkylation catalytic system, which involves the usually challenging 1,4-hydrogen atom abstraction (Scheme 119b). The reaction can be carried out under mild conditions with the support of optimal ligands to construct α,β -disubstituted cyclobutanones with high yield and excellent diastereo- and enantioselectivity. Using the strategy of cobalt-based metalloradical catalysis, Zhang's group [447,448] also realized the 1,5-C-H alkylation reaction using sulfonyl hydrazone as the precursor of the diazo compound (Scheme 119c, d). A series of five-membered

Figure 29 Water-soluble manganese porphyrins.

heterocyclic compounds were synthesized with high yield and excellent enantioselectivity.

8.2.3 Asymmetric amination of C–H bonds

In 1999, Che *et al.* [449] used chiral ruthenium (414) and manganese (415) porphyrins to catalyze the asymmetric amination of saturated C–H bonds in ethylbenzene and ethylnaphthalene, with 85% yield and 45%–58% ee (Scheme 120a). When using PhI(OAc)₂ as the oxidant, with the ruthenium porphyrin catalyst (414), the intramolecular asymmetric amination reaction can also be achieved, and the ee value was up to 87% (Scheme 120b) [450,451].

In 2019, Zhang *et al.* [452] activated sulfonyl azide with D_2 -symmetric chiral cobalt porphyrin complexes for enantioselective radical 1,5-C–H amination which stereoselectively constructed 5-membered cyclic sulfonic acid amides (Scheme 121a). Interestingly, the absolute configuration of the 1,5-C–H amination product of sulfamic acid azide can be controlled by tuning the length of the bridge and other remote nonchiral elements of the cobalt catalysts (Scheme 121b) [453]. In 2020, the same group successfully used the cobalt-based metalloradical catalytic system for the enantioconvergent radical amination of a racemic tertiary C(sp³)–H bond and constructed a chiral molecule with a quaternary stereocenter (Scheme 121c) [454]. Recently, they

Figure 30 Hydrogen bond-directed asymmetric carbon-hydrogen bond oxidation.

Scheme 118 Halterman porphyrin iridium-catalyzed asymmetric alkylation of C–H bonds (color online).

used alkoxysulfonyl azide derivatives derived from alcohols to perform asymmetric 1,5-C–H amination of alkoxysulfonyl azides with cobalt-based metalloradical catalysis to obtain five-membered chiral sulfamidates (Scheme 121d) [455], which can be used to deliver the corresponding chiral amino compound through the ring-opening reaction of the nucleophile.

Although significant progress has been made recently in intramolecular radical asymmetric C–H amination, intermolecular reactions remain a challenging problem. In 2020,

Scheme 119 Cobalt-based metalloradicals catalyze asymmetric C–H bond alkylation (color online).

Scheme 120 Halterman's metal-porphyrin catalyzed asymmetric C–H bonds amination (color online).

Zhang *et al.* [456] used the cobalt-based metalloradical catalytic system to realize the intermolecular asymmetric C–H amination reaction of carboxylic and fluoroaryl azides (Scheme 122). The reaction can be carried out under mild conditions and provides an efficient way to obtain valuable chiral amino acid derivatives with high enantioselectivity.

8.3 Metalloporphyrin-catalyzed asymmetric sulfoxidation

In 1990, Grove *et al.* [375] used the vaulted iron porphyrin complexes (**342**) developed by their research group to catalyze the oxidation of sulfur compounds. The reaction can

Scheme 121 Cobalt-based metalloradicals catalyze intramolecular asymmetric C–H bond amination (color online).

Scheme 122 Cobalt-based metalloradicals catalyze intermolecular asymmetric C–H bond amination.

produce the corresponding sulfoxide compounds in good yield, but its enantioselectivity is poor and the maximum ee value does not exceed 50% (Figure 31).

Naruta and Maruyama *et al.* [457,458] used their "twin crown" iron porphyrin (**343**) as a catalyst and iodoylbenzene as an oxidant to realize the asymmetric oxidation of sulfurcontaining compounds in the presence of 1-methylimidazole. The reaction showed good enantioselectivity and catalyst turnover (Figure 32).

In 2006 and 2011, Simonneaux's group used Halterman's metalloporphyrin catalysts (**370**) [394] and Halterman's water-soluble metalloporphyrin catalysts (**371**) [459] to achieve asymmetric oxidation of sulfides. Protonic solvents such as methanol and hydrogen peroxide can be used as oxidants when using water-soluble iron porphyrin catalysts, and the ee value of the reaction can reach up to 87% (Figure 33).

8.4 Summary and perspectives of heme-oxygenasebased biomimetic asymmetric catalysis

Although the catalytic chemistry that mimics heme oxidase began many years ago, the research progress in this field has

Ar ^{_S} ۲	342 (M Ph	= FeCl)	O " S R

Figure 32 Asymmetric oxidation of sulfides catalyzed by "twin crown" iron porphyrin (343).

been relatively slow and has been hindered by the difficulty in the synthesis of chiral porphyrin compounds. The structure and mechanism of such enzymes remain to be further understood to facilitate the design and the development of catalysts, but due to the inertness of C–H bonds and the small difference in the reactivity of different C–H bonds, the asymmetric oxidation of C–H bonds is extremely challenging. Therefore, it is urgent to develop a chiral biomimetic catalytic system with higher activity and better selectivity to solve the oxidation problems. There are very few catalytic

Figure 33 Asymmetric oxidation of sulfides with water-soluble metalloporphyrin catalysts (371).

systems that can effectively use O_2 as an oxidant. Therefore, the use of biomimetic strategies to achieve air oxidation of alkanes and alkenes will make the oxidation process more environmentally friendly and will have better industrial application value.

9 Nonheme oxygenase-based biomimetic asymmetric catalysis

There has been continued interest in the development of efficient catalysts for the enantioselective oxidation of organic molecules, since the resulting oxygenated motifs are prevalently found in pharmaceuticals and biologically active compounds [460-464]. In nature, nonheme iron enzymes that have iron active sites with a 2-His-1-carboxylate facial triad motif can carry out the highly selective O2-dependent C-H and C=C oxidation reactions in the important metabolic processes [465,466]. As shown in Scheme 123a, these enzymes activate O2 to generate high-valent iron(IV)-oxo species, thereby performing chemo- or enantioselective oxidation of various substrates. Actually, replicating the enzymatic reactivity with small artificial catalysts has been long recognized as an attractive strategy in oxidation chemistry [467]. Since the first crystal structure of a synthetic nonheme iron(IV)-oxo complex bearing a TMC ligand was reported in 2003 (Scheme 123b) [468], a great number of nonheme iron-oxo complexes, as well as other metal analogues, have been prepared, characterized, and investigated in various oxidation reactions [26]. These studies not only provided important insights into enzymatic pathways, but also offered valuable guidelines for the development of efficient oxidation catalysts. In addition to these characterizations of nonheme models, the use of nonheme

iron complexes for catalytic oxidations has increasingly drawn much attention. In the past several decades, a plethora of nonheme metal complexes supporting with chiral linear tetradentate nitrogen (N4) ligands have been proven powerful catalysts for asymmetric oxidation reactions [469–472]. In this section, we describe these advances in the chemical evolution of the catalysts as well as the biomimetic oxidation reactions.

9.1 Asymmetric epoxidation of olefins with nonheme metal complexes

Asymmetric epoxidation (AE) of olefins is one of the most important organic transformations, since the resulting enantiomerically pure epoxides are highly useful building blocks in organic synthesis [460,461]. Not surprisingly, numerous efforts have been dedicated to development of the efficient catalysts. Impressively, the groups of Jacobsen [473] and Katsuki [474] independently developed the salen-Mn(III) complexes for the AE of a variety of unfunctionalized alkenes. However, regarding the catalytic efficiency and the involvement of environmentally harmful oxidants, the current catalytic methods for AE of olefins mismatch the requirements for the green chemistry [471]. Definitively, hydrogen peroxide and dioxygen are the ideal oxidant choice owing to the production of water as a sole byproduct. In 1999, Jacobsen et al. [475] reported an iron-based system insitu generated from FeCl₂ and the polystyrene supported nitrogen ligands to perform the AE of olefins with hydrogen peroxide as the oxidant. A library of 5,760 ligand-metal complexes was rapidly screened by virtue of combinatorial chemistry (Scheme 124a). This pioneering work represented a significant step to emulate the reactivity of nonheme enzymes, although the level of enantiocontrol was still low. In 2001, Jacobsen and coworkers [476] demonstrated an iron (II)-mep complex for catalyzing epoxidation of olefins with H₂O₂ as the oxidant and acetic acid as a co-catalyst (Scheme 124b). This section will briefly introduce the well-defined iron and manganese complexes with chiral N4 ligands for the AE of olefins.

In 2003, Stack and coworkers [477] demonstrated that the manganese complex $Mn(R,R-mcp)(OTf)_2$ could efficiently catalyze the epoxidation of olefins with peracetic acid as the oxidant. However, they only examined the AE of vinyl cyclohexane to provide 10% ee (Figure 34, mcp). Along this vein, Costas and coworkers [478] modified the mcp ligand by fusing pinene rings at the pyridine moieties to afford a novel pinene-derived manganese complex. This complex provided a modest but remarkable enantioselectivity in ole-fin epoxidation (46% ee in the styrene epoxidation with peracetic acid). In 2009, Sun and coworkers [479] introduced aromatic groups into the framework of (*R*,*R*)-mcp to build a series of chiral N4 ligands (Figure 34, pmcp and bpmcp) and

Scheme 123 (a) The catalytic cycle of α -KG-dependent enzymes. (b) Several examples of N4 or N5 ligands (color online).

these manganese complexes epoxidized various electrondeficient olefins in excellent yields with high enantioselectivities (up to 89% ee). This method employed hydrogen peroxide as the terminal oxidant and 5 equiv. of acetic acid (AA) as an additive. Additionally, the corresponding iron complexes could promote the AE of α,β -unsaturated ketones with up to 87% ee [480]. Since White's group [481] reported the (*S,S*-pdp)-Fe complex for the selective oxidation of aliphatic C–H bonds in 2007, Bryliakov *et al.* [482] and Costas *et al.* [483] examined the manganese complexes of pdp and bpbpp ligands for AE of olefins (Figure 34, pdp and bpbpp). Indeed, these complexes bearing a rigid bipyrrolidine backbone showed improved enantioselectivity than that of chiral mcp-Mn complex. In order to improve stereo-induc-

Scheme 124 Pioneering work for iron-catalyzed epoxidation of olefins with H_2O_2 as the oxidant.

tion and catalytic efficiency, in 2012, Sun and coworkers [484] further prepared a C_1 -symmetric *S*-peb ligand derived from *L*-proline and benzimidazole (Figure 34, *S*-peb). The *S*-peb-Mn complex could work well in the AE of olefins even at 0.01 mol% of catalyst loading, providing up to turnover numbers (TONs) of 9,600 and up to 95% ee. They also tested the application for the synthesis of important intermediate epoxyketone of Carfilzomib. Subsequently, Sun's group [485] achieved the AE of olefins with up to 98% ee using *S*-peb-Fe complex as the catalyst.

R,R,R-bpbpp

Figure 34 Typical chiral N4 ligands used in the AE of olefins.

More importantly, in 2012, Bryliakov, Talsi, and coworkers [486] described that the steric bulk of the carboxylic acid additive could affect the enantioselectivity of the epoxidation. Among the examined carboxylic acids, 2ethylhexanoic acid (2-eha) led to the best stereocontrol. Therefore, they proposed that the carboxylic acid acted as a coligand coordinated to the possible Mn-oxo via an acidassisted mechanism (Scheme 125). After evaluation of substituents on the γ -pyridine at the pdp ligand, in 2013, Costas and coworkers [487] identified that Fe(^{Me2N}pdp) provided the best activity and enantioselectivity in the AE of olefins. Incorporation with suitable carboxylic acid, such as 2-eha and S-ibuprofen, a variety of olefins could be converted to the epoxides with high enantioselectivities (up to 99% ee). It should be noted that the electron-rich Fe(^{Me2N}pdp) catalyst allowed for the use of catalytic amount of carboxylic acid (3 mol%) in this AE process. Moreover, using the same iron catalyst and with N-protected amino acid as an acid partner, they realized the AE of challenging α -alkyl-substituted styrenes (Scheme 126, up to 97% ee) [488]. Bryliakov with coworkers [489] also investigated the effect of steric and electronic properties of bipyrrolidine-derived N4 ligands, and an electron-rich Mn(dmpdpn) complex facilitated the AE of olefins with high efficiency and enantiocontrol (TON up to 8,500, and up to 99% ee; Figure 34, dmpdpn). After further elaboration of chiral N4 ligand in combination with a benzimidazole and a bulky pyridine, Costas's group [490] realized the AE of cyclic aliphatic enones in high yields and up to 99% ee using $(R,R)^{Bz,TIPS}$ pdp-Fe catalyst (Scheme 127).

Apart from the use of carboxylic acid as the additive, Sun, Nam and coworkers [491] demonstrated that catalytic amount of sulfuric acid was suitable as the additive in the Mn-catalyzed asymmetric epoxidation. By employing arylsubstituted mcp-Mn complexes as the catalyst, typically (dbp-mcp)Mn(OTf)₂, the asymmetric epoxidation attained higher yields and enantioselectivities than those of catalytic systems using carboxylic acids. Computational mechanistic studies by density functional theory (DFT) suggested that a high-valent manganese(V)-oxo species can be generated as an epoxidizing intermediate *via* acid-promoted O–O bond heterolysis of a postulated Mn-OOH species (Scheme 128) [492].

The success of using the above chiral N4 metal catalysts in the asymmetric olefin epoxidations can be attributed to the reliable chiral N4 ligands and the key synergy of the carboxylic acid. Also, the structure of these iron and manganese catalysts is crucial to active oxidant. In principle, the linear N4 ligands in an octahedral coordination environment may exhibit *cis*- α , *cis*- β or *trans* topologies (Figure 35a) [493]. It is noteworthy that these above metal complexes exhibit a *cis*- α topology in which two potential *cis*-labile sites for the binding of both H₂O₂ and carboxylic acid facilitate the heterolytic O–O bond cleavage. Due to the lack of direct evi-

Scheme 125 Bulky carboxylic acid assisted AE of olefins with pdp-Mn complex.

Scheme 126 Synergistic interplay of a nonheme iron catalyst and N-protected amino acid for AE of α -alkyl-substituted styrene.

Scheme 127 AE of cyclic enones catalyzed by nonheme iron catalyst with H_2O_2 .

dence, Sun, Nam and coworkers [494] further investigated the mechanism by employing nonheme manganese catalysts with a chiral N4 (ProBn2Py) ligand and a N5 (Pro3Py) ligand (Figure 35b). Actually, the use of Mn-N5 catalyst cannot promote the epoxidation under the same reaction conditions as that of Mn-N4 catalyst.

Understanding the relationship between the ligand topologies and the reactivity of this class of metal complexes are important for the design of efficient bioinspired catalysts. More recently, Sun *et al.* [495] prepared a class of manganese complexes with 4-*tert*-Bu-phenyl-substituted mcp ligands, and the single-crystal X-ray analysis revealed these complexes adopted a special quasi-*trans* topology irrespective of the different groups on the pyridine donors and the coordinated anions. These quasi-*trans* topology manganese

Scheme 128 Possible intermediates for the (dbp-mcp) $Mn(OTf)_2$ with H_2O_2 in the presence of sulfuric acid (color online).

complexes could catalyze AE of olefins with H_2O_2 . Possibly, interconversion between quasi-*trans* and *cis*- α topologies could occur in the solutions (Scheme 129).

Despite these significant advances, these bioinspired catalysts still suffer from catalyst decomposition under oxidizing conditions. Gebbink and coworkers [496] disclosed a typical decomposition pathway *via* C–H oxidation on the 2pyridinylmethylene sites of the complexes by the active oxidants generated *in situ*. In this context, Sun and coworkers [497] prepared a series of porous organic polymer-supported Mn-N4 catalysts in which the single-site catalytic units were dispersed in the skeleton of porous organic polymers. As expected, these porous single-site Mn-N4 catalysts demonstrated excellent activity and recyclability in both C–H oxidation and AE reactions. Considering the enantioinduction, efficiency, and substrate scope, these above achievements

Scheme 129 AE of olefins catalyzed by a quasi-trans Mn-N4 complex (color online).

represent the state-of-the-art progress in the field of asymmetric olefin epoxidation. Encouragingly, on the basis of AE catalytic system by Sun's group [484,498], Walker *et al.* recently accomplished the kilogram-scale synthesis of the epoxyketone of carfilzomib with a 0.04 mol% loading of chiral Mn-N4 catalyst [499].

9.2 Asymmetric *cis*-dihydroxylation of olefins with nonheme metal complexes

Among the methods for functionalization of olefins, asymmetric *cis*-dihydroxylation of olefins is a powerful tool to introduce both stereo- and enantiospecific diol units into organic molecules. Sharpless asymmetric dihydroxylation of olefins using OsO_4 and chiral phthalazine ligands has proven the most successful approach [500]. The environmentally

Figure 35 (a) Possible topologies for octahedral metal complexes with linear N4 ligands. (b) Mechanistic studies with N4/N5 manganese complexes (color online).

benign metal catalyst is still demanding due to the toxicity and cost of osmium reagent. In this context, Rieske dioxygenases, having a mononuclear iron center to a 2-His-1carboxylate motif, can perform the cis-dihydroxylation of C=C bonds in the biodegradation of arenes [501,502]. Inspired by these unique property, in 2001, Que and coworkers [503] demonstrated the first example of an Fe-catalyzed asymmetric cis-dihydroxylation of olefins with Fe(S,S-6- Me_2 -BPMCN)(OTf)₂ as the catalyst and H_2O_2 as the oxidant (Figure 36). In the case of asymmetric *cis*-dihydroxylation of trans-2-octene, 82% ee was obtained. However, olefin should be used in a 50-fold excess with respect to the oxidant. In 2008, they realized the asymmetric cis-dihydroxvlation of olefins in up to 97% ee using $Fe^{II}(R,R-6-Me_2-$ BPBP)(OTf)₂ catalyst, wherein a rigid bipyrrolidine was involved in the chiral N4 ligand (Figure 36) [504]. In 2011, a more practical method for asymmetric cis-dihydroxylation of electron-deficient olefins was developed by Che and coworkers [505]. This method employed a Mn-(S,S-BQCN) complex as the catalyst and Oxone as the oxidant to provide the chiral diols with up to 96% ee.

Along the same line, in 2016, Che and coworkers [506] investigated a variety of substituted R,R-BQCN-Fe(OTf)₂ complexes for the asymmetric cis-dihydroxylation of olefins. Among these complexes, $Fe-(R,R-2-Me_2-BQCN)(OTf)_2$ complex showed outstanding performance in the asymmetric cis-dihydroxylation of olefins under substrate-limiting conditions (Figure 36, up to 99.8% ee). Notably, various simple olefins could be well tolerated, for example, the reaction of trans-4-octene afforded the desired product in 99% ee. In a subsequent study, they modified this BQCN-type ligands with classic 1,2-diphenylethane-1,2-diamine backbone instead of cyclohexane-1,2-diamine to get several novel substituted BQPN ligands. A variety of trisubstituted electrondeficient olefins could be efficiently oxidized to chiral cisdiols with high yields and enantioselectivities using Fe-(R,R-2-Me₂-BOPN)(OTf)₂ as the catalyst (Figure 36, up to 99.9%) ee) [507]. More recently, Wang, Nam and coworker [508] reported the asymmetric cis-dihydroxylation of substituted aliphatic acrylates to produce a diverse set of cis-2,3-dihydroxy esters by using the $[Fe-(R,R-2-Me_2-BQCN)(MeCN)_2]$ $(ClO_4)_2$ (Figure 36). In these reactions, the iron complex with perchlorate counteranions is more reliable than that of Fe-(R, R)R-2-Me₂-BQCN)(OTf)₂. This above asymmetric cis-dihydroxylation method based on the nonheme iron catalysts and H₂O₂ represent a green and practical approach. The success strongly depends on the elaboration of the chiral N4 ligands.

9.3 Asymmetric C–H oxidation catalyzed by nonheme metal complexes

The enantioselective oxidation of C–H bonds offers a direct yet challenging tool for the transformation of organic mo-

Figure 36 Chiral N4-Fe catalysts used in the asymmetric *cis*-dihydrox-ylation.

lecules into chiral oxygen-containing compounds [509,510]. In nature, heme and nonheme enzymes that oxygenate a variety of organic compounds with high efficiency and specificity have thus inspired the intensive biomimetic studies over the several past decades. In 1989, Groves and coworkers [436] demonstrated the first example of asymmetric hydroxylation of ethylbenzenes by a chiral iron-porphyrin. According to the C-H bond hydroxylation by highvalent metal-oxo complexes, it follows the H-atom abstraction and subsequent oxygen-rebound mechanism that has been well-established in heme systems [511]. However, the enantioselective oxidation of C-H bonds has long been a formidable challenge, especially in the unactivated C-H bond oxidation. In this regard, more reliable chiral catalysts are highly desirable. The intensive studies of chiral N4 ligands and their oxidation catalysis indeed provide the opportunities to accomplish the enantioselective oxidation of C-H bonds in some types of substrates. Since the selective oxidation of aliphatic C-H bonds with (S,S-pdp)-Fe complex was reported by White *et al.* [481] in 2007, surprisingly, no further investigation on the enantioselective oxidation of aliphatic C-H bonds was attempted for a long time. In 2012, Bryliakov and coworkers [512] investigated the stereospecific oxidation of aliphatic C-H with mcp-Mn or pdp-Mn (typically, with 0.1 mol% loading) and H₂O₂ in the presence of acetic acid. Later, Sun and coworkers [513] reported the efficient benzylic and aliphatic C-H oxidation in methylenic sites with proline-derived pmb-Mn complex and H₂O₂. To a large extent, these studies trigger the subsequent enantioselective oxidation of C-H bonds due to the attractive reactivity of these manganese complexes.

In 2017, Costas, Bietti and coworkers [514] achieved the enantioselective aliphatic C-H oxidation with a $Mn(S,S^{-TIPS}ecp)$ complex to prepare a series of monosubstituted N-cyclohexylalkanamides. After a systematic survey of iron, manganese complexes as well as carboxylic acid partners, they identified the catalytic system with $Mn(S.S^{-TIPS}ecp)$ complex and cycloproanecarboxylic acid to achieve high level of siteand enantioselective C-H oxidation (Scheme 130). In the same year, Sun and Nam [515] reported the kinetic resolution of racemic secondary alcohols with previous (R,R-dbp-mcp) Mn(OTf)₂/H₂O₂/H₂SO₄ catalytic system. Actually, the oxidation of racemic secondary alcohols also involved the enantioselective C-H oxidation. DFT calculations revealed that the energy barriers for the α-C-H bond activation of 1phenylethanol (R- and S-enantiomers) by a high-valent manganese-oxo species are significantly different. Bryliakov and coworkers [516] also explored the enantioselective benzylic hydroxylation of arylalkanes with a trifluoroethoxysubstituted Mn(^{TFE,Me}pdp) complex as the catalyst and N-Boc-(S)-proline as the acid additive, affording 1-arylalkanols in up to 86% ee. In 2018, Sun, Nam and coworkers [517] established a useful method for the enantioselective oxidation of benzylic methylene in spirocyclic precursors to produce chiral spirocyclic β , β' -diketones with high yields and enantioselectivities, wherein S-peb-Mn complex was proved to be a suitable catalyst (Scheme 131). This catalytic system was also applicable to the enantioselective oxidation of spirocyclic oxindoles and quinolinones. According to the asymmetric oxidation of spirocyclic quinolinones, the corresponding alcohols could be obtained in up to 99% ee [518]. In 2019, Costas, Bietti and coworkers [519] reported the enantioselective lactonization of unactivated methylenes in up to 99% ee via a Mn-catalyzed C-H oxidation directed by carboxylic acids (Scheme 132a). More recently, they further expanded this strategy to modify α -amino acids and α, α disubstituted α -amino acids. In the cases of α , α -disubstituted α -amino acids, lactonization of γ -methylenic site provided the desired products with outstanding diastereo- and enantioselectivity (up to 97% ee) [520]. In these approaches, fluorinated alcohol, such as 2,2,2-trifluoroethanol (TFE), was selected as the solvent, and it might assist H₂O₂ activation as well as the subsequent lactonization of the resulting hydroxy acid because of its mild acidity and high polarity. They also showed that TFE as reaction solvent enhanced the aliphatic hydroxylation selectivity in the Mn-catalyzed aliphatic C-H bond oxidation [521]. Bryliakov and coworkers [522] further examined the benzylic hydroxylation of arylalkanes in fluorinated alcohols, and up to 89% ee was observed with 2,2-difluoroethanol as the reaction solvent. Subsequently, they established a one-pot sequential asymmetric hydroxylation/oxidative kinetic resolution approach for the synthesis of chiral alcohols, where hexafluoroisopropanol was used as a solvent (Scheme 132b)

[523]. Prompted by these achievements, Sun and coworkers [524] recently reported the diastereo- and enantioselective hydroxylation of benzylic methylene C–H bonds of indanederived ketones catalyzed by the *S*-peb-Mn complex. By employing TFE as the reaction solvent, the benzylic alcohols were furnished in high levels of diastereoselectivities (up to >95:5) and enantioselectivities (up to 95% ee) (Scheme 133).

9.4 Summary and perspectives of nonheme oxygenasebased biomimetic asymmetric catalysis

Nature has evolved unique ability to perform an array of metabolically vital oxidative transformations by using ironcontaining enzymes, thereby offering a strong basis for developing efficient oxidation catalysts. In the past two decades, we have witnessed the rapid growth in the field of asymmetric oxidation reactions with chiral nonheme iron and manganese complexes. Remarkably, a great number of chiral linear N4 ligands have been designed and prepared, and their metal complexes such as Fe and Mn have shown versatile and unprecedented performance in asymmetric olefin epoxidation, cis-dihydroxylation, and enantioselective C-H oxidation reactions. The success was strongly inspired by the introduction of chiral linear N4 ligands that feature facile structural modification in both electronic and steric properties. Despite significant advances, we cannot neglect the catalyst decomposition because of the generation of highly active oxidants under oxidizing conditions. Therefore, how to address this paradox existing in the oxidation catalysis remains a demanding task. It is anticipated that there will be a solution for the access of more efficient oxidation catalysis.

10 Biomimetic asymmetric catalysis mediated by dinuclear & multinuclear metal complexes

Conventionally, the metal-based catalysts used in asymmetric transformations consist of a single metal center supported by a chiral ligand. Despite tremendous progress in this area, there are still a number of important asymmetric reactions that lack of efficient chiral catalysts. As an important source of inspiration for the development of artificial chiral catalysts, Nature has already developed some specific and highly selective catalysts for reactions that are difficult to achieve in organic chemistry, namely, metalloenzymes containing two or more metal ions in proximity as their active sites (Figure 37) [525]. The metal centers in these metalloenzymes usually demonstrate cooperative effects by synergistic interaction with the reactants, thus achieving amazing efficiency and outstanding selectivity in the catalysis. For example, the urease was known to catalyze the conversion of urea to ammonia and carbon dioxide via the cooperative action of the two nickel(II) centers in the process. Imitating the dinuclear active sites of biocatalysts, the development of chiral dinuclear/multinuclear metal complexes for asymmetric catalysis has attracted great attention, owing to the potential synergistic effects between the metal centers for the activation of reagents in a chiral environment, and thus may achieve enhanced catalytic activities and selectivities compared with the traditional approach based on mononuclear systems. Herein, some representative applications of (bio-inspired) chiral bi- or multi-metallic catalysts in the area of asymmetric catalysis are highlighted.

10.1 Chiral multimetallic self-assembled complexes developed by Shibasaki group

Shibasaki's group pioneered the use of multifunctional homo- and hetero-metallic catalysts in asymmetric transformations. In 1992, Shibasaki and coworkers [526] reported a groundbreaking study using a BINOL-based polymetallic complex as the catalyst for asymmetric nitroaldol reaction, which generally contains one rare metal, three alkali metals and three chiral BINOL units (Scheme 134a). The bifunctional nature of this type of catalysts, *i.e.*, the Lewis acidity at the lanthanide center and Brønsted basicity at the alkoxide sites counterbalanced by the proximal alkali metal cations, was believed to be crucial for the catalysis, enabling a high yield (91%) and excellent enantioselectivity (90% ee) of the reaction. Soon after, the same group disclosed an asymmetric conjugate addition of malonates to α . β-unsaturated ketones using similar multimetallic catalyst, with Na⁺ ions as the alkali metal cations in this case (Scheme 134b), giving the corresponding products in high yields (89%–98%) with good to excellent enantioselectivities (72%–92% ee) [527]. Since then, a series of multimetallic complexes self-assembled in situ from various rare earth-and alkali metals with BINOLs, linked-BINOLs, and dinucleating Schiff bases have been developed by Shibasaki's group and successfully applied as catalysts in a variety of enantioselective transformations, including nitroaldol reaction, direct aldol reaction, Michael reaction, epoxidation of enones, epoxide opening reaction, Diels-Alder reaction, nitro-Mannich reaction, cyanosilylation of aldehydes and ketones, Strecker reaction, and Reissert reaction, and these achievements have been well summarized in several excellent reviews (Scheme 134c) [528].

Figure 37 Selected examples of the metalloenzymes containing binuclear sites (color online).

10.2 Chiral metallosalen-type bimetallic systems

Chiral metallosalen complexes have been widely used as a class of privileged catalysts in asymmetric catalysis [529]. Interestingly, cooperative bimetallic reaction mechanisms, in which both the electrophile and the nucleophile are activated simultaneously by two catalyst molecules, have been established in several transformations catalyzed by metallosalens [530]. Jacobsen's group have made seminal contributions to the studies on asymmetric catalysis using bimetallic salen metal complexes, typically comprising of two or more metallosalen moieties tethered together in the catalyst skeleton by a linker unit, which demonstrated greatly enhanced reactivity as compared with monomeric catalysts and often with improved enantioselectivity. The first example reported by Jacobsen's group [531] in 1998 was a series of dinuclear Cr(salen) complexes of covalently linked dimeric salen ligand used for the asymmetric ring opening of epoxides by trimethylsilly azide (Scheme 135a). Besides the asymmetric epoxide ring-opening reactions, oligomeric metallosalen catalysts have also displayed enhanced efficiency in asymmetric conjugate addition of trimethylsilyl cyanide to α_{β} unsaturated carbonyl derivatives and enantioselective intramolecular ring-opening reaction of oxetanes [532]. In 2010, Ding and coworkers [533] reported a dimeric titanium complex in which the two salen units were connected through a covalent tether, which was demonstrated to be one of the best catalysts developed so far for the enantioselective cyanation of aldehydes in terms of catalytic efficiency, enantioselectivity and substrate adaptability (Scheme 135b).

Chiral metallosalen-type bimetallic systems have also been successfully applied in the enantioselective polymerization of epoxides. In 2010, Coates and coworkers [534] reported an asymmetric catalytic ring-opening polymerization of a variety of monosubstituted epoxides using an enantiopure bis(salencobalt) complex as a highly active catalyst, leading to the formation of enantiopure epoxides and isotactic polyethers from racemic epoxides (Scheme 136a). In this case, a covalently tethered bimetallic complex featuring a chiral binaphthol linker was proved to be highly active and selective in this reaction. In 2013, Lu and coworkers [535] reported a chiral catalyst system based on enantiopure dinuclear Salen-Co(III) complexes, which exhibited excellent activity and high enantioselectivity in desymmetrization copolymerization of meso-epoxides with CO_2 to give optically active polycarbonates (Scheme 136b). Later, Lu's group [536] also developed the synthesis of stereoregular polyesters by the asymmetric copolymerization of meso-epoxides and cyclic anhydrides using catalyst systems based on enantiopure bimetallic Salen complexes.

10.3 Chiral dinuclear ProPhenol/Zn catalysts

In 2000, Trost and coworkers [537] developed a chiral Pro-Phenol/Zn catalyst (Scheme 137a) for enantioselective direct aldol reactions between aryl methyl ketones and aldehydes, affording the chiral aldol adducts in good yields with high enantioselectivities (Scheme 137b). As a member of the chiral aza-crown family, the ProPhenol ligand can spontaneously form a bimetallic complex upon treatment with an alkyl metal reagent such as Et₂Zn. The resulting complex features Lewis acidic and Brønsted basic sites, thus both nucleophile and electrophile can be simultaneous activated in the same chiral environment, allowing for new bond formation in a highly effective and stereoselective manner. Upon treatment of the *in situ* prepared catalyst solution with p-nitrophenol, Ding and coworkers [538] successfully elucidated the dinuclear structure of a chiral ProPhenol/Zn-type catalyst via X-ray analysis in 2005. After Trost's seminal work, this type of prominent dinuclear metal-ProPhenol catalysts have been successfully used in a variety of enantioselective reactions such as desymmetrization of mesodiol, alkynylation, Mannich, Henry and Friedel-Crafts re-

(c) Multimetallic complexes developed by Shibasaki group

Scheme 135 Selected examples of asymmetric catalytic reactions with chiral bimetallic salen complexes (color online).

actions, and much of the progress has been well summarized in an excellent review by Trost and coworkers [539]. In 2021, Huang and coworkers [540,541] reported an elegant reductive desymmetrization of malonic esters catalyzed by a dinuclear zinc complex with an unsymmetrical tetradentate chiral ligand (Scheme 137c). The reduction features excellent enantiocontrol that can differentiate sterically similar substituents and high chemoselectivity towards the diester

Scheme 136 Chiral bimetallic salen catalysis in enantioselective polymerization.

Scheme 137 Chiral ProPhenol/Zn catalysts in asymmetric synthesis (color online).

motif, giving α -quaternary β -hydroxyesters in good yields with excellent ee values. In 2021, Trost *et al.* [542] reported the development of a modified ProPhenol ligand by replacing one of the chiral prolinol arms with a chiral NHC moiety, the so-called NHC-ProPhenol ligand, which was found to facilitate the formation of the hetero-bimetallic Zn-Cu catalyst (Scheme 137d). This chiral Cu/Zn heterobimetallic complex has been successfully applied in the asymmetricallylic alkylation reactions of allyl phosphates with zinc keto-homoenolates, leading to the formation of various γ -vinyl ketones in good regio- and enantio-selectivities.

10.4 Other selected chiral dinuclear metal catalysts

In 2002, Gong and coworkers [543] reported an enantioselective oxidative coupling of 2-naphthol derivatives, using oxovanadium complexes derived from chiral biphenol or binaphthol as the catalysts and air or oxygen as the terminal oxidant (Scheme 138). An intramolecular radicalradical coupling pathway involving catalytic species bearing two vanadium metal centers was suggested as the key step in this reaction. A closely related homodinuclear vanadium-Schiff base complex for oxidative coupling reactions was also reported by Sasai and coworkers [544].

In 2003, Martell and coworkers [545] reported the use of a structurally defined chiral dinuclear Cu complex as the precatalyst for the asymmetric oxidative coupling of 2-naphthol, leading to the formation of binaphthol in good yield and good enantioselectivity (Scheme 139). In this catalyst structure, two Cu metal centers are bound by two N_2O_2 moiety in the cavity formed in the fused chiral polyamino macrocycle ligand.

In 2008, Peters and Jautze [546] reported the use of a planar-chiral ferrocenyl bispalladacycle for the catalytic enantioselective Michael addition of trisubstituted α -cyanoacetates to enones, affording the corresponding Michael adducts with excellent yields (TONs up to 2450) and high enantioselectivities (Scheme 140). It was proposed that the α -cyanoacetate can be activated by coordination of the nitrile moiety to one Pd^{II} center, while the enone might be simultaneously activated by coordination of the olefinic double bond to the carbophilic Lewis acid Pd^{II}, thus leading to superior catalytic activity and a high level of stereocontrol.

Zhang and coworkers [547] reported in 2012 the development of a chiral bimetallic Ru catalyst based on a ruthenocenyl phosphino-oxazoline ligand (RuPHOX), which showed good activity and high enantioselectivity in asymmetric hydrogenation of various C=O and/or C=C substrates. It should be highlighted that this bimetallic Ru catalyst has been applied in the synthesis of dihydroartemisinic (DHAA) in 98% yield with 99.7:0.3 er, a key intermediate for the synthesis of artemisinin (Scheme 141) [548]. Under otherwise identical conditions, the corresponding mono-Ru-PHOX/Ru complex gave lower reaction activity and inferior enantioselectivity compared with the binuclear catalyst, suggesting that the both Ru atoms of the RuPHOX-Ru act as catalytic sites and are essential for the excellent catalytic behavior, which is proposed to improve the catalytic activity and to establish a bulkier steric hindrance.

In 2015, Bhadra, Yamamoto and coworkers [549] reported

Scheme 138 Enantioselective oxidative coupling reactions catalyzed by chiral binuclear oxovanadium complexes (color online).

Scheme 139 Chiral binuclear Cu catalyzed asymmetric oxidative coupling.

Scheme 140 The asymmetric Michael addition reaction catalyzed by a planar-chiral ferrocenyl bispalladacycle.

Scheme 141 RuPHOX-Ru catalyzed asymmetric hydrogenation as a key step for the synthesis of DHAA.

a highly regio- and stereoselective epoxidation of homoallylic alcohols catalyzed by a binuclear titanium complex, formed with a chiral ligand featuring two 8-quinolinol moieties tethered on a BINOL backbone (Scheme 142). It was proposed that one of the metal centers can act as a Lewis acid to bind with the hydroxy moiety of the alkenol substrate, while the other metal center can draw the electrophilic oxidant in proximity to the olefin site, and thus may facilitate the reaction to occur.

In 2020, Stoltz, Hong and coworkers [550] reported the use of a salen nickel catalyst, featured by the presence of polyether functionalities that may act as crown-ether-like cationbinding site for alkali ions, for the enantioselective alkynylation of trifluoromethyl ketones (Scheme 143), leading to the formation of chiral trifluoromethyl substituted tertiary alcohols in high yields (up to 99%) with high enantioselectivities (up to 97% ee). It was proposed that the salen ligand framework with a pendant crown ether can interact with an alkali metal cation to form a Ni^{II}/K⁺ heterobimetallic catalyst, which can facilitate the cooperative catalysis, as the Lewis acid and Brønsted base moieties could be held in close proximity by a rigid structure.

10.5 Chiral binuclear complexes containing metalmetal bonds

Besides the examples shown above, several chiral binuclear metal complexes with metal-metal bonds have also been reported to be useful in asymmetric catalysis [551]. A representative example is the well-established class of chiral dirhodium(II) paddlewheel complexes, which have been demonstrated as exceptionally versatile catalysts for a wide range of transformations, including fascinating C–H bond functionalization and cycloaddition such as aziridination and cyclopropanation *via* Rh(II) nitrenoid and carbenoid intermediates [552].

Other types of metal-metal bond based chiral binuclear complexes have also been developed, showing unique catalytic activities and good chiral induction in asymmetric catalysis. Nishibayashi and Hidai et al. [553] reported catalytic propargylic substitution reactions with various nucleophiles using alkanethiolate-bridged diruthenium complexes [Cp*RuCl(SR)]₂. The chiral thiolate bridged diruthenium complexes bearing a phenethyl alcohol derivative were reported by the Nishibayashi group's in 2005, demonstrating good enantioselectivities (up to 82% ee) in the catalytic propargylic substitution reactions of propargylic alcohols with acetone (Scheme 144) [554]. The attractive C–H/ π interaction between the C-H bond of the terminal phenyl group in the thiolate ligand and the π -system of the benzene ring on the allenylidene complex was proposed to play a key role to control the stereoselectivity. These chiral thiolate-bridged diruthenium complexes have also been successfully used in other asymmetric intermolecular and intramolecular propargylation reactions by Nishibayashi and coworkers [555]. In 2014, Uyeda's group [556] reported the synthesis of

Scheme 142 Asymmetric epoxidation of homoallylic alcohols catalyzed by a titanium complex of a binucleating chiral multidentate ligand (color online).

Scheme 143 Enantioselective alkynylation of trifluoromethyl ketones enabled by a Ni^{II}/K^+ heterobimetallic catalyst.

Scheme 144 Asymmetric propargylic substitution reactions catalyzed by chiral alkanethiolate-bridged diruthenium complexes (color online).

dinuclear Ni(I) complexes of a naphthyridine diamine (NDI) ligand, and metal-metal bonding interaction was found to exist in the resulting structures. These dinickel complexes were employed as catalysts for [4+1]-cycloaddition reactions of 1,3-dienes and 1,1-dichloroalkenes [557]. Ni(I)-Ni(I) bonds can be retained in the catalytic process due to the redox activity of the NDI ligands. In 2020, Uyeda's group [558] synthesized a new class of dinickel complexes of NDI ligands, containing two chiral oxazolyl units anchored on a naphthyridyl skeleton, which were used as catalysts in enantioselective intermolecular [4+1]-cycloadditions reaction of vinylidene equivalents and 1,3-dienes, providing the corresponding cycloadducts with ee values of up to 98% (Scheme 145a). In the same year, Cramer and co-workers [559] reported a novel class of chiral naphthyridyl diimine ligands readily accessible from the chiral C_2 -symmetric 2,6di-(1-arylethyl) anilines. These ligands were used in a re-

Scheme 145 Asymmetric cycloaddition reactions catalyzed by chiral dinickel complexes (color online).

ductive [Ni]₂-catalyzed enantioselective alkylidene transfer reaction from 1,1-dichloroalkenes to olefins, giving a broad range of synthetically valuable alkylidenecyclopropanes in high yields and enantioselectivities (up to 96:4 er) (Scheme 145b).

10.6 Summary and perspectives of biomimetic asymmetric catalysis mediated by dinuclear & multinuclear metal complexes

Inspired by the salient catalytic performance of some multinuclear metalloenzymes in nature, the development of chiral catalysts containing two or more metal sites have attracted significant attention in the field of asymmetric catalysis. Some successful examples of asymmetric catalysis featured by the use of bi- or multi-metallic complexes as catalysts have been reported so far and have demonstrated substantially enhanced catalytic efficiencies and/or higher selectivities than their mono-nuclear counterpart complexes in some types of reactions. Despite the huge potential in this area, progress in the field of asymmetric catalysis by dinuclear/multinuclear metal complexes lags far behind the prominent position of mono-nuclear transition metal complexes, probably as a result of difficulties in effective construction of well-defined chiral multinuclear complexes, and the lacking of mechanistic understanding of the potential synergistic cooperations.

11 Conclusions and outlooks

Over the past several decades, much progress has been made in the area of biomimetic asymmetric catalysis. By mimicking various significant enzymes, many biomimetic catalysts, including organo and metallic categories, have been developed. Although biomimetic catalysts are much smaller than the corresponding enzymes, many of them have displayed impressive enzyme-like features, such as high catalytic activity, excellent diastereo- and enantiocontrol, and environmentally friendly reaction conditions. Biomimetic asymmetric catalysis has been grown into unique and powerful tools for the construction of chiral C–C, C–O, C–N and C–X bonds and it has been widely utilized in the synthesis of complicated bioactive compounds.

Despite much remarkable progress achieved, biomimetic asymmetric catalysis is still at the early stage of development. Many grand challenges await further studies to address. First of all, as compared to thousands of natural enzymes, the enzymes well-mimicked are still very limited so far. Many significant enzymes are still waiting for biomimetic studies to develop new chemistry of asymmetric catalysis. Secondly, in terms of catalytic activity, most of the biomimetic catalysts are far below the level of the corresponding enzymes. Improvement of the catalytic efficiency to the level of enzymes needs more efforts. In addition, currently, biomimetic asymmetric catalysis was developed mainly by mimicking of the catalytic centers of enzymes, sometimes together with the imitation of the cooperative catalytic functions of amino acid residues. Actually, the catalytic cavity constructed by protein skeletons also plays an important role in substrate recognition, reaction activation, and chiral induction for enzymatic catalysis. Thus, introducing a suitable chiral pocket should be a highly promising startegy for the enhancement of the performance of biomimetic catalysts; however, it remains to be one of the most formidable challenges in the area of biomimetic chemistry. Finally, up to now, the development of efficient biomimetic catalysts still mainly depends on trial-and-error screening. Rational design has contributed little to this area so far. It would play an increasingly important role in the future along with more mechanistic understanding of the relationship between the structure and function of chiral biomimetic catalysts.

Opportunities always coexist with challenges. These problems also represent future directions of development in the field of biomimetic asymmetric catalysis. Considering the huge diversity and the extraordinary catalytic power of enzymes, chemists may get inexhaustible inspirations from enzymes and they would have unlimited motivations to continue to contribute their wisdom and efforts for developing more efficient new biomimetic catalysts. Undoubtedly, biomimetic asymmetric catalysis is growing into a powerful and green platform for the synthesis of chiral molecules with biological and chemical significance.
